Background: *Glaesserella parasuis* (*G. parasuis*) is a respiratory pathogen of swine and the etiological agent of Glässer's disease. The structural organization of genetic information, antibiotic resistance genes, potential pathogenicity, and evolutionary relationships among global *G. parasuis* strains remain unclear. The aim of this study was to better understand the genetic variation, antibiotic resistance, and virulence mechanisms of *Glaesserella parasuis* (*G. parasuis*).

Methods: The whole-genome sequence of a ST328 isolate from diseased swine in China was then compared with 54 isolates from China sequenced in this study and 39 strains from China and other 8 countries sequenced by others in order to better understand the genetic variation, antibiotic resistance, and virulence mechanisms of *G. parasuis*.

Results: The ST328 genome contained a novel Tn6678 transposon harboring unique resistance determinants. It also contained a small broad-host-range plasmid pYL1 carrying *aac(6')-Ie-aph(2'')-Ia* and *bla_{ROB-1}* that was transferred to *Staphylococcus aureus* RN4220 by electroporation and was highly stable under kanamycin selection. The diversity and wide variation of *G. parasuis* are mainly reflected in the accessory genomes (85.13–91.74%). Phylogenetic analysis revealed two major subgroups associated with country, serotypes, and MLST. Novel virulence factors (*gigP*, *malQ*, and *gmhA*) and drug resistance genes (*norA*, *bacA*, *ksgA*, and *bcr*) were identified. Resistance determinants (*sul2*, *aph(3'')-Ib*, *norA*, *bacA*, *ksgA*, and *bcr*) were widespread across isolates, regardless of serovar, isolation source, or geographical location.

Conclusions: Our comparative genomic analysis of worldwide *G. parasuis* isolates to date provides valuable insight into the emergence and transmission of *G. parasuis* in the swine industry. The result suggests the importance of genomic variations, especially transposon-related and/or plasmid-related gene variations, in the evolution of *G. parasuis*.

Abstract:

Background: *Glaesserella parasuis* (*G. parasuis*) is a respiratory pathogen of swine and the etiological agent of Glässer's disease. The structural organization of genetic information, antibiotic resistance genes, potential pathogenicity, and evolutionary relationships among global *G. parasuis* strains remain unclear. The aim of this study was to better understand the genetic variation, antibiotic resistance, and virulence mechanisms of *Glaesserella parasuis* (*G. parasuis*).

Methods: The whole-genome sequence of a ST328 isolate from diseased swine in China was then compared with 54 isolates from China sequenced in this study and 39 strains from China and other 8 countries sequenced by others in order to better understand the genetic variation, antibiotic resistance, and virulence mechanisms of *G. parasuis*.

Results: The ST328 genome contained a novel Tn6678 transposon harboring unique resistance determinants. It also contained a small broad-host-range plasmid pYL1 carrying *aac(6')-Ie-aph(2'')-Ia* and *bla_{ROB-1}* that was transferred to *Staphylococcus aureus* RN4220 by electroporation and was highly stable under kanamycin selection. The diversity and wide variation of *G. parasuis* are mainly reflected in the accessory genomes (85.13–91.74%). Phylogenetic analysis revealed two major subgroups associated with country, serotypes, and MLST. Novel virulence factors (*gigP*, *malQ*, and *gmhA*) and drug resistance genes (*norA*, *bacA*, *ksgA*, and *bcr*) were identified. Resistance determinants (*sul2*, *aph(3'')-Ib*, *norA*, *bacA*, *ksgA*, and *bcr*) were widespread across isolates, regardless of serovar, isolation source, or geographical location.

Conclusions: Our comparative genomic analysis of worldwide *G. parasuis* isolates to date provides valuable insight into the emergence and transmission of *G. parasuis* in the swine industry. The result suggests the importance of genomic variations, especially transposon-related and/or plasmid-related gene variations, in the evolution of *G. parasuis*.

Introduction

Glaesserella parasuis, a gram-negative bacterium of the family *Pasteurellaceae*, is a respiratory pathogen that affects swine. It is the etiological agent of Glässer's disease, which can lead to pneumonia without signs of systemic disease [1]. As China is one of the world's largest pork producers, with more than 463 million pigs accounting for approximately 50% of the global population [2], *G. parasuis* represents a significant threat to pig health and economic loss worldwide [3]. Penicillins and aminopenicillins are common treatments for *G. parasuis* infections [4], and clinical strains resistant to β -lactams and aminoglycosides have been reported in several countries [5-8].

Whole-genome sequencing (WGS) has revealed that the diversity and wide variation among *G. parasuis* strains are mainly reflected in their accessory genomes, which occupy a large fraction (~86%) of the gene content compared with the core genome [9]. The accessory genes are also associated with serovar-specific genes, including capsule genes and putative virulence factors [9]. A comparative study of five pathogenic *G. parasuis* strains of three serovars from diseased pigs in Japan, China, and the USA demonstrated high genomic diversity among the strains, which was partly attributed to a high number of mobile genetic elements such as transposons and bacteriophages; moreover, 4–6% of the analysed genomes comprised strain-specific accessory genes [10]. WGS analyses on 11 *G. parasuis* strains from Japan, USA, China, Germany, Sweden, and Switzerland identified several noteworthy differences in coding regions, including genes for outer membrane, metabolism, and pilin or adhesin-related genes [3]. Another study revealed that the toxin-antitoxin systems between phenotypically distinct *G. parasuis* strains from Japan and Sweden had genomic differences [11].

Antibiotic resistance in *G. parasuis* is mainly conferred by a combination of transferable antibiotic resistance genes (ARGs) and multiple target gene mutations. For instance, to date, two β -lactam resistance genes (*bla*_{ROB-1} and *bla*_{TEM}) and an aminoglycoside-resistance gene (*aac* (6')-Ib-cr) have been identified in *G. parasuis* [7, 12, 13]. Moreover, the multi-resistant efflux pump AcrB may have an impact on the emergence of resistance in *G. parasuis*. Additionally, putative

compensatory mechanisms to overcome fitness impairment coinciding with the acquisition of resistance have been described for some drugs [2, 14].

However, the structural organization of genetic information, ARGs, potential pathogenicity, and evolutionary relationships among global *G. parasuis* strains remain unclear. Therefore, in this study, we sequenced a multidrug-resistant isolate from diseased swine in Dongguan, China, which was compared with 54 isolates from China sequenced by us and 39 strains from China and other 8 countries sequenced by others in order to improve our understanding and provide information for gaining better control to treat these infections.

Materials & Methods

Isolates

The multidrug-resistant *G. parasuis* isolate (HPS-1) of serotype 4 examined in this study was originally isolated from the lungs of a pig suffering from Glässer's disease in a commercial pig farm in Dongguan city, Guangdong province, China, in 2017. The isolate was resistant to β -lactams, aminoglycosides, macrolides, quinolones, lincomycin, and sulfonamides as determined by the disc agar diffusion method and the broth microdilution method (Table S1) [15].

The other 54 *G. parasuis* isolates were obtained from diseased pigs from more than 20 geographically dispersed farms in China between November 2007 and May 2017 (Table S2). Bacteria were identified by biochemical tests and 16S diagnostic PCR [6, 16]. All 55 *G. parasuis* isolates were characterised using serotyping and MLST as previously described [17, 18].

Genome sequencing, assembly, and bioinformatics analysis

G. parasuis isolates were cultured on tryptic soy agar or in tryptic soy broth (Oxoid, Hampshire, UK) supplemented with 10 mg/mL nicotinamide adenine dinucleotide and 5% bovine serum at 37°C in 5% CO₂ for 24 h. Total genomic DNA was extracted using the DNeasy DNA extraction kit (Axygen, Union City, CA, USA).

Among the 55 isolates, one multidrug-resistant isolate (HPS-1) and one sensitive isolate (HPS-2) from diseased swine in Guangdong were randomly selected for WGS using the PacBio RSII (Pacific Biosciences, MenloPark, CA, USA) and Illumina MiSeq (Illumina, San Diego, CA, USA) platforms as previously described [19]. The genome assemblies of HPS-1 generated in this study were deposited in GenBank under accession number CP040243. The plasmid pYL1 and transposon Tn6678 of HPS-1 were submitted to GenBank under accession number MK182379 and MK994978, respectively. Gene prediction and annotation were performed as previously described [19]. Genomic libraries of the other 53 genomes were prepared and sequenced as previously described [20]. WGS data were assembled *de novo*, and gene prediction and annotation were performed as previously described [21].

Phylogenetic and clustering analyses

Two phylogenetic trees were constructed to assess the relatedness of the 55 *G. parasuis* strains with 39 available, previously published, genome sequences (Table S2) using single-copy core orthologs and SNPs with the maximum-likelihood optimality criterion using PhyML v3.0; the SNP tree was virtually rooted using *Glaesserella* sp.15-184 as an outgroup [22]. The gene contents of all 94 isolates were compared using cd-hit (v 4.6.1) software, which utilizes protein sequences to effectively generate non-paralogous gene clusters (identity ≥ 0.8 , $\geq 80\%$ the length of the longest cluster).

The search scope was limited to 65% identity to determine the phylogenetic profile of *bcr*. Multiple sequence alignment was performed with MUSCLE in MEGA 7.0, resulting in 92 candidate genes. The neighbour-joining phylogenetic tree was constructed in MEGA 7.0 with 1000 bootstrap replicates.

Comparison of antimicrobial resistance and virulence genes

A whole-genome Blast [23] search (E-value $\leq 1e^{-5}$, minimal alignment length percentage $\geq 80\%$) was performed against four databases for pathogenicity and drug resistance analysis: Pathogen Host Interactions (PHI), Virulence Factors of Pathogenic Bacteria (VFDB),

122 Carbohydrate-Active enZymes Database (CAZy), and Integrated Antibiotic Resistance Genes
123 Database (IARDB). (see supplementary method for details)

124 **Features of the novel Tn6678 transposon in HPS-1**

125 Based on the results of the BLASTn search, the genomic characteristics were compared
126 among four isolates that harboured a transposon Tn6678-like structure. BLASTn searches were
127 performed to identify genes homologous to *bcr*, encoding the multidrug efflux system BCR/CflA,
128 which were aligned by MUSCLE in MEGA 7.0 and adjusted manually. The default parameter
129 for both gap open and gap extend was -400. The phylogenetic tree was constructed using the
130 neighbour-joining method in MEGA 7.0 with 1000 bootstrap replicates.

131 **Electrotransformation and plasmid stability test**

132 To determine the contributions of pYL1 to penicillin and aminoglycoside antibiotic
133 resistance, electrotransformation experiments were performed using *Staphylococcus aureus*
134 RN4220 as the recipient as previously described [24]. Transformants were selected on brain-heart
135 infusion (BHI) agar supplemented with kanamycin (25 µg/mL) for colony growth at 37°C for 16
136 h. Transformation efficiency was calculated based on the ratio of transformants to the total
137 number of viable cells. The presence of the *aac(6')-Ie-aph(2'')-Ia* and *bla_{ROB-1}* genes in
138 transformants was confirmed by PCR amplification followed by DNA sequence analysis. The
139 MICs of *S. aureus* RN4220 and five transformants were determined by Etest (Liofilchems.r.l.)
140 according to the manufacturer's instructions.

141 The stability of plasmids carrying *aac(6')-Ie-aph(2'')-Ia* and *bla_{ROB-1}* was determined by
142 serial passages for 15 consecutive days at 1:1000 dilutions into fresh BHI, with or without
143 antibiotic (kanamycin) pressure. Serially diluted cultures were spread on BHI agar plates with or
144 without kanamycin (8 µg/mL), and the resistance retention rate was determined by randomly
145 picking at least 50 colonies from the BHI plates, spotting them onto new BHI plates with
146 kanamycin (8 µg/mL), and calculating the ratio of resistant to total colonies. Both the resistant
147 and susceptible colonies from the plates were randomly picked and subjected to PCR for

148 detection of *bla*_{ROB-1} and *aac*(6')-Ie-aph(2'')-Ia.

149 **Results and discussion**

150 ***G. parasuis* core and unique genes**

151 Compilation of the 94 genomes covering all serovars and disease- and non-disease-causing
152 backgrounds from nine geographic locations (Table S2) demonstrated expansion of the pan-
153 genome, whereas the number of core genes remained relatively stable with the addition of new
154 strains (Fig. 1A). This suggested the possibility of open pan-genomes experiencing frequent
155 evolutionary changes through gene gains and losses or lateral gene transfers for efficient
156 environmental adaptation. The size of the pan-genome was 5,243 genes, including 175 core
157 genes shared among the 94 isolates (Fig. 1B). By contrast, 1,049 core genes were previously
158 identified among 212 *G. parasuis* isolates from the UK (n = 121), Argentina (n = 1), Belgium (n
159 = 1), China (n = 2), Denmark (n = 29), Germany (n = 6), Greece (n = 1), Italy (n = 2), Japan (n =
160 7), Spain (n = 21), Sweden (n = 4), Switzerland (n = 2), the USA (n = 6), and unknown origins
161 (n=9) [9]. The diversity and wide variation were mainly reflected in the accessory genomes,
162 occupying a large fraction (85.13–91.74%) of the *G. parasuis* gene content compared with the
163 core genomes (Table 1). The number of unique genes ranged from 0 in 10 strains to 103 in strain
164 D74, indicating that 0–4.6% of the genomes consisted of strain-specific accessory genes (Table
165 1). This further indicated the possibility of frequent horizontal gene transfer events in *G.*
166 *parasuis*; thus, investigating the source of this variation is critical to understanding the adaptive
167 potential of this species.

168 Clusters of Orthologous Groups classification indicated that core genes were significantly
169 enriched in defense mechanisms and inorganic ion transport and metabolism, whereas unique
170 genes were significantly enriched in unknown function, nucleotide transport and metabolism,
171 and carbohydrate transport and metabolism (Fig. 1C).

172 **Phylogenetic analysis of *G. parasuis* isolates**

The core gene sequence-based phylogeny for our isolates and reference isolates is shown in Fig. 2. This tree resolved two strongly structured lineages, lineages I and II, with each subgroup comprising multiple closely related isolates. This pattern was similar to a UPGMA-based dendrogram that exhibited two main clades, but differed from the population grouping predicted by MLST, which showed six main subgroups [18].

Phylogenetic lineages exhibited association with country, serotypes, and MLST types (Fig. 2). There was a certain degree of geographic structure, with a greater proportion of Chinese isolates in both clades, likely due to a larger proportion of Chinese isolates in the collection. This was analogous to the phylogenetic tree of the *G. parasuis* core genome built from concatenated core genes [9, 18]. Lineages I and II comprised eight and two countries, respectively. The fact that strains from different regions belonged to the same clade of the whole-genome phylogenetic tree suggested frequent migration of isolates between geographic regions. Serovars 5, 12, and 14 were identified predominantly in lineage I, while serovars 2 and 10 were mostly found in lineage II. For serovars 3, 8, 9, and 11, the numbers of isolates were too low to be able to restrict them to one clade. The remainder of the serovars were found in both clades. MLST analysis allocated the 39 isolates in GenBank to 13 unknown STs and 20 different STs, including six new STs, and the 55 isolates obtained in our study belonged to 49 different STs, including 39 new STs (Table S2).

Thus, the results of this study enrich the *G. parasuis* MLST databases and highlight the wide distribution of *G. parasuis* strains. Most strains of the same STs formed single clades, and there was no definitive association between STs and serotypes (Fig. 2), consistent with previous studies [18, 25]. The SNP-based tree with and without an outgroup (Fig. S1 and Fig. S2) was consistent with the phylogenetic analysis based on single-copy core orthologs. The number of whole-genome SNP differences among the 94 isolates ranged from 8,603 to 8,730.

Biological features of *G. parasuis* isolates

Variations in virulence and stress resistance genes were observed among *G. parasuis* lineages and subgroups (Fig. 3). All 94 *G. parasuis* isolates harboured more than five types of

pathogenic factors. The virulence factors *gigP*, *malQ*, and *gmhA* were carried by all the tested *G. parasuis* isolates. Moreover, the virulence factors *rfa* cluster, encoding enzymes for LPS core biosynthesis of *G. parasuis* [26], and *galU* and *galE*, resulting in impaired biofilm formation, were universally present in the *G. parasuis* isolates. The *rfaF* gene has been linked to serum resistance, adhesion, and invasion; *galU* plays a role in autoagglutination and biofilm formation; whereas *galE* appears to affect biofilm production indirectly in *G. parasuis* [27]. Serum resistance may play a role in the virulence of *G. parasuis* [28]. However, *lsgB*, previously associated with *G. parasuis* virulence potential, was predominant in six isolates (29755 and HPS9 from the USA, Nagasaki from Japan, and KL0318, SH0104, and SH0165 from China), in line with potentially virulent strains isolated from the nasal cavities of healthy pigs [29, 30].

The sulfonamide resistance gene (*sul2*), β -lactam-resistant genes (*pbp1a*, *pbp3a*), and aminoglycoside resistance factors (*aph(3'')-Ib*) were universally present in the *G. parasuis* isolates (Fig. 3). The main ARGs associated with resistance in *G. parasuis*, including the β -lactam-resistant gene, tetracycline resistance genes, aminoglycoside resistance genes, fluoroquinolone resistance gene, chloramphenicol resistance genes, and two efflux pump genes mentioned above were discovered among these isolates (Fig. 3). The *bla_{ROB-1}*, *sul2*, *aph(3'')-Ib*, *tetB*, *aac(6')-Ie-aph(2'')-Ia*, *catIII*, and *floR* genes have previously been identified in *G. parasuis* [8]. The three different serotype isolates (H82, H92, and H313) obtained from different sites in different years that clustered closely in one branch all harboured the lincosamide antibiotic resistance factor *lunC*, which was contained in the ISSag10 sequence of all three isolates (Fig. 3). The *lunC* gene was also identified in plasmid pHN61 of *G. parasuis* [31]. Moreover, 91.5% of the isolates had *bcr*, 90.42% of the isolates had *bacA*, 100% of the isolates had *ksgA*, but five isolates had *norA*, which have not previously been reported in *G. parasuis*.

Genomic features of *G. parasuis* HPS-1

Following sequencing and assembly, a 2,326,414-bp chromosome with an average G+C content of 40.03%, and a 7,777-bp small plasmid sequence (pYL1) with an average G+C content of 33.32% were identified in strain HPS-1 (Supplementary Fig. S3 and Fig. 4). HPS-1 exhibited

a novel ST (ST328) with undescribed MLST alleles or previously unreported allelic combinations. This ST328 genome harbored resistance genes against several types of antibiotics, including sulfonamides (*sul2*), aminoglycosides (*aph(3'')-Ib*, *aac(6')-Ie-aph(2'')-Ia*), and β -lactam (*bla_{ROB-1}*) (Table S1). Further, this genome contained efflux pump-related genes that confer resistance to sulfonamides (*bcr*) and multidrug resistance (*acrB*).

We also identified a novel transposon in the ST328 isolate, designated Tn6678 in the Tn Number Registry (<https://transposon.lstmed.ac.uk/>). This transposon harbours two 966-bp IS110 family transposases at both ends, two toxin genes, two genes associated with the two-component signal transduction system, one efflux pump-associated gene, and four genes encoding hypothetical proteins with unknown function (Fig. 5). Genome analysis revealed that Tn6678 was inserted between the molybdopterin molybdotransferase MoeA encoded by *moeA* and 3-isopropylmalate dehydratase large subunit encoded by *leuC*. A LacI family transcriptional regulator and a bifunctional tRNA (5-methylaminomethyl-2-thiouridine)(34)-methyltransferase MnmD/FAD-dependent 5-carboxymethylaminomethyl-2-thiouridine (34) oxidoreductase MnmC flanked the transposon to the right and left, respectively.

Through BLASTN searches, highly conserved homologous sequences to Tn6678 (>97% nucleotide sequence similarity) were identified in four *G. parasuis* strains [29755 (GenBank accession number CP021644, USA), SH0165 (CP001321, China), ZJ0906 (CP005384, China), and str. Nagasaki (NZ_APBT00000000, Japan)]. The only differences in these five chromosomes were in the transposases, but transposon Tn6678 had two complete inverted repeats of IS110 transposases flanked by 32-bp inverted repeats of ISNme5 at both ends (Fig. 5), suggesting mobility potential. The *bcr*-containing Tn6678 also contained an antibiotic resistance gene cassette, suggesting its potential to transfer antibiotic resistance genes.

The clinical isolate *G. parasuis* HPS-1 also harbours two drug resistance genes (*cpxA* and *cpxR*) and an efflux pump gene (*bcr*) organized within a putative complete transposon. Association between the Cpx system and bacterial antimicrobial resistance has been reported in *Escherichia coli*, *Salmonella enterica*, *Klebsiella pneumoniae*, and *G. parasuis* [32-36]. CpxR

plays essential roles in mediating macrolide resistance (i.e., erythromycin) [36]. The Bcr/CflA efflux system was identified as a group of antiporters that confer resistance to chloramphenicol, florfenicol, and bicyclomycin by actively transporting these compounds out of the cell [37].

BLASTn searches for the *bcr* gene returned a large set of divergently related sequences using default parameters. These sequences were annotated as bicyclomycin/multidrug efflux system, Bcr/CflA family drug resistance efflux transporter, Bcr/CflA family multidrug efflux MFS transporter or drug resistance transporter, and Bcr/CflA subfamily. Phylograms revealed that the *bcr* gene in HPS-1 was most closely related to homologues identified in other members of the Pasteurellaceae, particularly *G. parasuis*, *Actinobacillus indolicus*, *Bibersteinia trehalosi*, *Actinobacillus* (*A. pleuropneumoniae*, *A. suis*, *A. equuli*, *A. lignieresii*, *A. indolicus*, and *A. porcitis*), and *Mannheimia* (*M. haemolytica* and *M. varigena*), all of which are known causative agents of upper respiratory tract infections (Fig. 6).

In *G. parasuis*, only the efflux pump AcrB, belonging to the RND family, has been analysed to date. Efflux pump AcrB may play a role in multidrug resistance, and the *acrAB* gene cluster could affect the efflux of macrolides in *G. parasuis* [14]. However, this is the first description of the efflux pump Bcr/CflA in *G. parasuis*, belonging to the MFS. This efflux encoded by *bcr* was shown to be involved in bicyclomycin (sulfonamide) resistance, and its presence on a transposon indicated its potential transferability.

The neighbour-joining phylogenetic tree using 92 *bcr* genes selected from the BLASTn searches clearly demonstrated two distinctive clades. The first clade contained *bcr* genes of *Hemophilus influenzae*, which colonizes humans, and other bacteria that colonize animals. Members of the second clade were divided into four apparent subclades, including *G. parasuis*, *B. trehalosi*, *Actinobacillus* spp., and *Mannheimia* spp. Except for *G. parasuis*, the chromosomally encoded Bcr/CflA from *G. parasuis* HPS-1 most closely clustered with that found in *A. indolicus*. The phylogenetic tree indicated a divergent evolutionary pattern between animal-origin *Pasteurellaceae* bacteria.

General features and electrotransformation of the plasmid pYL1

The plasmid pYL1 identified in HPS-1 contained seven ORFs with an average length of 912 bp, with one encoded protein of undetermined function (Fig. 4), and two antimicrobial resistance genes, *bla*_{ROB-1} and *aac*(6')-Ie-aph(2'')-Ia. The ROB-1 of plasmid pYL1 had a typical size of 305 bp, in line with functionally active members of the ROB-1 family from different plasmids in *Pasteurellaceae* species. AAC(6')-Ie-APH(2')-Ia, the most important aminoglycoside-resistance enzyme in gram-positive bacteria conferring resistance to almost all known aminoglycoside antibiotics in clinical use, also had a typical size of 479 amino acids in this family [38]. Four ORFs were identified to encode a 3'-truncated transposase protein ISAp11 (30 amino acids), a Rep-like protein (444 amino acids) involved in plasmid replication, and two Mob proteins, MobC (144 amino acids) and MobA (541 amino acids), associated with plasmid mobilization (Fig. 4). To date, two β -lactam resistance genes (*bla*_{ROB-1} and *bla*_{TEM}) have been reported in *G. parasuis* [13]. A β -lactam resistance plasmid, pB1000, harbouring *bla*_{ROB-1} was detected in *G. parasuis* clinical strains isolated from Glässer's disease lesions [7]. Although *aac*(6')-Ib-cr is considered the most prominent aminoglycoside-resistance gene in *G. parasuis* [7, 12], the bifunctional aminoglycoside-resistance enzyme AAC(6')-Ie-APH(2')-Ia in plasmids is also reported in GenBank for *G. parasuis* strains.

Except for resistance genes, pYL1 had the same backbone and genetic structure and showed 100% nucleotide identity to four plasmids, namely pFZ51, pFS39, pHN61, and pHB0503 (Table S3) [31, 39, 40]. Further, the pYL1 segment of the resistant genes and its flanking region exhibited $\geq 58\%$ sequence homology to these four plasmids (Fig. 7), suggesting evolution among these small plasmids.

The transposase gene of ISAp11 in pYL1 had an internal deletion of 659 bp, and the 3' and 5' ends were intact. The truncated ISAp11 linked with *bla*_{ROB-1} suggested that ISAp11 played a key role in transposition of *bla*_{ROB-1} by facilitating the horizontal transfer of β -lactam and aminoglycoside resistance among *G. parasuis* isolates and it was also found in *A.*

porcitonsillarum or *G. parasuis* plasmids pFJS5863, pQY431, and pFS39. However, the function of ISAp11 requires further investigation.

Transformation of pYL1 into *S. aureus* RN4220 was achieved at a frequency of 10^{-9} cells per recipient cell by electroporation. Hence, pYL1 is a mobilizable plasmid with active mobilization genes. The transformants had increased MICs for oxacillin, gentamicin, amikacin, kanamycin, and streptomycin as compared with those of the parental strain (0.047 to > 256 mg/L, 0.094 to 1.5 mg/L, 0.38 to 16 mg/L, 0.38 to 32 mg/L, and < 0.25 to 32 mg/L, respectively). This finding indicated that plasmid pYL1 carrying *bla*_{ROB-1} and *aac*(6')-Ie-aph(2'')-Ia contributed to the penicillin resistance and aminoglycoside antibiotic resistance of *S. aureus* RN4220 transformants. Furthermore, the plasmid showed low stability in *S. aureus* without antibiotic pressure, as only 52.5%, 30.48%, and 2.68% of transformants maintained the kanamycin resistance after five, six, and seven subcultures, respectively. However, the plasmid can be conserved in *S. aureus* cultured with kanamycin, as 100% of the colonies remained resistant to kanamycin after 10 subcultures, confirmed by PCR mapping.

Conclusions

In summary, our results shed new light on the importance of genomic variations, especially transposon-related and/or plasmid-related gene variations, in the evolution of *G. parasuis*. This comparative analysis identified potential novel virulence factors (*gigP*, *malQ*, and *gmhA*) and drug resistance genes (*norA*, *bacA*, *ksgA*, and *bcr*) in *G. parasuis*. Resistance determinants (*sul2*, *aph*(3'')-Ib, *norA*, *bacA*, *ksgA*, and *bcr*) were widespread across isolates, regardless of serovar, isolation source, or geographical location. Future research focused on a larger sample of *G. parasuis* isolates worldwide is necessary to gain a better understanding of the rapid development of antibiotic resistance associated with mobile genetic elements in *G. parasuis* based on WGS analysis.

Figure 1(on next page)

Analysis of the core and pan-genome of *G. parasuis* isolates.

(A) Core and pan-genomic calculations in *G. parasuis* isolates. Each green point represents the number of genes conserved between genomes. All of the points are plotted as a function of the strain number(x). The deduced pan-genome size: $P(x) = 2483.54x^{0.18} - 461.72$. The height of the curve continues to increase because the pan-genome of *G. parasuis* is open. (B) Genes missing or present in *G. parasuis* isolates. The heat map illustrates the distribution of core and accessory genes across the *G. parasuis* strains. The columns represent *G. parasuis* isolates. The rows represent genes. The red and black regions represent the presence or absence of genes in a particular genome, respectively. The black regions indicate features missing in that strain but present in one or more of the other *G. parasuis* strains. (C) The distribution of all, core, and specific genes according to the COG classification. The y-axis indicates the percentage of genes in various COG categories. J: Translation, ribosomal structure and biogenesis. A: RNA processing and modification. K: Transcription. L: Replication, recombination and repair. B: Chromatin structure and dynamics. D: Cell cycle control, cell division, chromosome partitioning. Y: Nuclear structure. V: Defense mechanisms. T: Signal transduction mechanisms. M: Cell wall/membrane/envelope biogenesis. N: Cell motility. Z: Cytoskeleton. W: Extracellular structures. U: Intracellular trafficking, secretion, and vesicular transport. O: Posttranslational modification, protein turnover, chaperones. C: Energy production and conversion. G: Carbohydrate transport and metabolism. E: Amino acid transport and metabolism. F: Nucleotide transport and metabolism. H: Coenzyme transport and metabolism. I: Lipid transport and metabolism. P: Inorganic ion transport and metabolism. Q: Secondary metabolites biosynthesis, transport and catabolism. R: General function prediction only. S: Function unknown.

Each green point represents the number of genes conserved between genomes. All of the points are plotted as a function of the strain number(x). The deduced pan-genome size: $P(x) = 2483.54x^{0.18} - 461.72$. The height of the curve continues to increase because the pan-genome of *G. parasuis* is open. (B) Genes missing or present in *G. parasuis* isolates. The heat map illustrates the distribution of core and accessory genes across the *G. parasuis* strains. The columns represent *G. parasuis* isolates. The rows represent genes. The red and black regions represent the presence or absence of genes in a particular genome, respectively. The black regions indicate features missing in that strain but present in one or more of the other *G. parasuis* strains. (C) The distribution of all, core, and specific genes according to the COG classification. The y-axis indicates the percentage of genes in various COG categories. J: Translation, ribosomal structure and biogenesis. A: RNAprocessing and modification. K: Transcription. L: Replication, recombination and repair. B: Chromatin structure and dynamics. D: Cell cycle control, cell division, chromosome partitioning. Y: Nuclear structure. V: Defense mechanisms. T: Signal transduction mechanisms. M: Cell wall/membrane/envelope biogenesis. N: Cell motility. Z: Cytoskeleton. W: Extracellular structures. U: Intracellular trafficking, secretion,

and vesicular transport. O: Posttranslational modification, protein turnover, chaperones. C: Energy production and conversion. G: Carbohydrate transport and metabolism. E: Amino acid transport and metabolism. F: Nucleotide transport and metabolism. H: Coenzyme transport and metabolism. I: Lipid transport and metabolism. P: Inorganic ion transport and metabolism. Q: Secondary metabolites biosynthesis, transport and catabolism. R: General function prediction only. S: Function unknown.

Figure 2

Maximum-likelihood phylogeny of 94 *Glaesserella parasuis* isolates based on 93 single-copy core genes.

The annotation rings surrounding the tree, from outside to inside, depict (1) geographic region, (2) year of sample collection, (3) site of sample, and (4) serotype. The different colors of the branches represents lineage.

Figure 3

Virulence and resistance profiles across the phylogeny of the 94 *G. parasuis* isolates.

Cluster analysis based on single-copy core orthologs. Pattern of gene presence (colored line) or absence (white).

Figure 3. Virulence and resistance profiles across the phylogeny of the 94 *G. parasuis* isolates. Cluster analysis based on single-copy core orthologs. Pattern of gene presence (colored line) or absence (white).

Figure 4

Schematic map of plasmid pYL1.

The circles show, from outside to inside: first and second, putative open reading frames, the positions and orientations of the genes; third, G+C content (deviation from the average); and, fourth, G+C skew (green, +; purple, –).

Figure 4. Schematic map of plasmid pYL1. The circles show, from outside to inside: first and second, putative open reading frames, the positions and orientations of the genes; third, G+C content (deviation from the average); and, fourth, G+C skew (green, +; purple, -).

Figure 5

Organization of the *G. parasuis* HPS-1 Tn6678 transposon and comparison with the similar structure.

ORFs are shown as arrows, indicating the transcription direction, and the colors of the arrows represent different fragments. Gene color code: transposase, purple; toxin genes (*pilT* and *phd*), yellow; resistance genes(*cpxA*, *cpxR* and *bcr*), blue; proteins with other or unknown functions, gray. Homologous gene clusters in different isolates are shaded in gray (>97%).

Figure 5. Organization of the *G. parasuis* HPS-1 Tn6678 transposon and comparison with the similar structure. ORFs are shown as arrows, indicating the transcription direction, and the colors of the arrows represent different fragments. Gene color code: transposase, purple; toxin genes (*pilT* and *phd*), yellow; resistance genes(*cpxA*, *cpxR* and *bcr*), blue; proteins with other or unknown functions, gray. Homologous gene clusters in different isolates are shaded in gray (>97%).

Figure 6

Neighbor-joining phylogenetic tree based on bcr gene sequences obtained from the current study and downloaded from NCBI.

The trees were constructed using MEGA version 7.0 with 1,000 bootstrap replicates. The *G. parasuis* HPS-1 is indicated by a solid circle.

Figure 6. Neighbor-joining phylogenetic tree based on *bcr* gene sequences obtained from the current study and downloaded from NCBI. The trees were constructed using MEGA version 7.0 with 1,000 bootstrap replicates. The *G. parasuis* HPS-1 is indicated by a solid circle.

Figure 7

Comparison of the genetic structures of pHN61, pFS39, pYL1, pFZ51 and pHB0503.

The accession numbers and origins of these plasmids are displayed on the left side. Arrows represent putative open reading frames, the positions and orientations of the genes. Blue arrows indicate Rep-like protein involved in plasmid replication. Green arrows indicate hypothetical protein. Regions with 98% nucleotide sequence identity are shaded grey.
