Background. The unconscious processing of information is an important skill used by competitive athletes to handle the rapidly changing movements of opponents and equipment. Previous studies have shown that unconscious executive control among athletes is better than that among non-athletes in the sports-specific domain. However, it is not yet clear whether athletes also show superior unconscious executive control in the general cognitive domain.

Methods. Twenty-five competitive table tennis players (athletes) and 26 aged-matched non-athletic college students (non-athlete controls) were recruited for this study. Participants first performed a masked priming task that used geometric shapes as primes and targets to examine unconscious executive control in the general cognitive domain. As a control, participants then completed a prime identification task to determine whether they could consciously detect the priming geometric forms. Reaction times and error rates were analyzed to examine whether motor expertise influenced unconscious processing in the general domain.

Results. The use of signal detection analyses for the performance of participants to identify the masked primes indicated that neither athletes nor non-athletes could consciously perceive the priming stimuli ($p > 0.05$ for both groups). Two-way repeated-measures analyses of variance followed by simple effects analyses of the results of the masked priming task indicated that athletes responded faster (mean \pm standard error: congruent, 489.15 ± 9.75 ms; incongruent, 500.33 ± 8.99 ms; $p < 0.001$) and committed fewer errors (congruent, $13.00\% \pm 1.59\%$; incongruent, $26.36\% \pm 2.08\%$; $p < 0.001$) when the priming stimulus was congruent with the target stimulus than when the stimuli were incongruent. These results indicated a significant unconscious response priming effect of geometric forms among athletes. By contrast, non-athletes did not respond faster or commit fewer errors for congruent vs. incongruent conditions. No significant difference was detected between athletes and non-athletes in overall reaction times and error rates for congruent trials, but athletes committed significantly more errors than non-athletes on incongruent trials ($p < 0.01$).

Conclusion. The results indicated that motor expertise facilitated the unconscious processing of geometric forms, suggesting that the influence of motor expertise on unconscious executive control occurs not only for the sports-specific domain but also for the general cognitive domain.

Motor expertise affects the unconscious processing of geometric forms

Abstract

Background. The unconscious processing of information is an important skill used by competitive athletes to handle the rapidly changing movements of opponents and equipment. Previous studies have shown that unconscious executive control among athletes is better than that among non-athletes in the sports-specific domain. However, it is not yet clear whether athletes also show superior unconscious executive control in the general cognitive domain.

Methods. Twenty-five competitive table tennis players (athletes) and 26 aged-matched non-athletic college students (non-athlete controls) were recruited for this study. Participants first performed a masked priming task that used geometric shapes as primes and targets to examine unconscious executive control in the general cognitive domain. As a control, participants then completed a prime identification task to determine whether they could consciously detect the priming geometric forms. Reaction times and error rates were analyzed to examine whether motor expertise influenced unconscious processing in the general domain.

Results. The use of signal detection analyses for the performance of participants to identify the

masked primes indicated that neither athletes nor non-athletes could consciously perceive the priming stimuli ($p > 0.05$ for both groups). Two-way repeated-measures analyses of variance followed by simple effects analyses of the results of the masked priming task indicated that athletes responded faster (mean \pm standard error: congruent, 489.15 ± 9.75 ms; incongruent, 500.33 ± 8.99 ms; $p < 0.001$) and committed fewer errors (congruent, $13.00\% \pm 1.59\%$; incongruent, $26.36\% \pm 2.08\%$; $p < 0.001$) when the priming stimulus was congruent with the target stimulus than when the stimuli were incongruent. These results indicated a significant unconscious response priming effect of geometric forms among athletes. By contrast, non-athletes did not respond faster or commit fewer errors for congruent vs. incongruent conditions. No significant difference was detected between athletes and non-athletes in overall reaction times and error rates for congruent trials, but athletes committed significantly more errors than non-athletes on incongruent trials ($p < 0.01$).

Conclusion. The results indicated that motor expertise facilitated the unconscious processing of geometric forms, suggesting that the influence of motor expertise on unconscious executive control occurs not only for the sports-specific domain but also for the general cognitive domain.

1. Introduction

Previous studies have shown that behavior can be influenced by visual stimuli that are not consciously perceived; that is, individuals can encode information that lies below their threshold for conscious awareness (Ortells, Kiefer, Castillo, Megias, & Morillas, 2016; Tseng et al., 2016; Zovko & Kiefer, 2013). In competitive sports, athletes, especially those engaged in sports that require open skills, process movement information unconsciously most of the time because of the limited time available before the athletes must react (Kibele, 2006). A widely used paradigm to study unconscious processing in executive control is the masked priming task (Kiefer, 2012; Kiefer & Martens, 2010). The unconscious response priming effect is considered an indirect measure to evaluate processing of the masked primes (Ansorge, Kunde, & Kiefer, 2014). With the masked priming paradigm, recent studies found that athletes exhibit stronger unconscious

response priming effects than non-athletes in a sport-specific domain, suggesting that athletes show superior unconscious executive control owing to their extensive specialized training (Gueldenpenning, Braun, Machlitt, & Schack, 2015; Meng, Li, You, & Xie, 2019). However, whether athletes also show superior unconscious executive control in the general domain is still unknown.

Recent studies have suggested that expertise or practice may be an important prerequisite for unconscious processing (Heinemann, Kiesel, Pohl, & Kunde, 2010; Kiesel, Kunde, Pohl, Berner, & Hoffmann, 2009; Reuss, Kiesel, Pohl, & Kunde, 2015). Athletes are considered experienced individuals because of the extensive motor expertise they have accumulated during their years of training (Guo, Li, & Yu, 2017; Voss, Kramer, Basak, Prakash, & Roberts, 2010). Additionally, unconscious executive control is an important skill that enables athletes to deal with rapidly changing movement information (Gueldenpenning, Koester, Kunde, Weigelt, & Schack, 2011; Kibele, 2006). Hence, researchers are beginning to investigate the relationship between motor expertise and unconscious executive control. For example, using the masked priming task, Meng et al. (2019) investigated unconscious executive control in table tennis players. Their results showed that table tennis players unconsciously perceive visuospatial information and show significant unconscious response priming effect, whereas the control nonathletic college students did not. Gueldenpenning et al. (2015) also examined unconscious processing of complex movements by using a similar method. They found that compared with novices, athletes involved in martial arts training were able to distinguish feint and non-feint actions unconsciously and to initiate a faster motor response. Some researchers have suggested that the high perceptual sensitivity and the perceptual-motor common representations among athletes may well explain their superiority in unconscious processing (Gueldenpenning et al., 2011). However, the stimuli that were used in these aforementioned studies are associated with the sports-specific domain. Whether the effect of motor expertise can be transferred from a sports-specific domain to a general domain has not been systematically investigated.

A study conducted by You et al. (2018) using a general masked go/no-go task to examine

motor expertise and unconscious response inhibition found that table tennis athletes have superior unconscious response inhibition compared with non-athletes. That study provided initial evidence that the superiority of unconscious executive control performance in athletes may not be confined to the sport-specific domain. However, unconscious response inhibition is only one subprocess of unconscious executive control. Other subprocesses, such as updating representations in working memory and switching between tasks or mental sets (Miyake et al., 2000), should also be considered before it is known whether athletes compared with non-athletes show superior unconscious executive control in the general domain.

The present study aimed to examine whether motor expertise facilitates unconscious executive control in a general masked priming task that uses stimuli unrelated to sports. Thus, we recruited a group of competitive table tennis players and a group of aged-matched college students without a specific motor expertise to perform a masked priming task and a control prime visibility task. We hypothesized that both athletes and non-athletes would respond faster and commit fewer errors on trials in which prime and target stimuli were congruent than when they were incongruent, displaying a significant unconscious response priming effect. We further hypothesized that the strength of this unconscious response priming effect in athletes would be stronger than that in non-athletes.

2. Materials and Methods

2.1 Participants

Twenty-five age-matched competitive table tennis players (9 females; mean age, 20.44 years with a range of 18-23 years) and 26 college students (10 females; mean age, 19.85 years with a range of 18-22 years) were recruited for this study. The competitive table tennis players were considered athletes, and the college students were considered non-athlete controls. All athletes had obtained the first or second level of the national standard, with a mean table tennis training

experience of 7.96 years. The non-athletes had no practical experience with any sports. All participants were right-handed, had normal or corrected-to-normal vision, and had no psychiatric or neurologic illness. All participants provided written informed consent prior to starting the experiment and received financial compensation after finishing the experiment. This study received approval from the Ethics Committee of Shanghai University of Sport (No. 2018025).

2.2 Stimuli and equipment

On the basis of previous studies (Ulrich & Kiefer, 2016; Zovko & Kiefer, 2013), we selected images of four black geometric forms (circle, diamond, ellipsoid, and square) as primes and targets. Two images that contained many randomly oriented lines were designed as masks. The stimuli (including masks) were presented on a gray background (RGB values of 128,128, and 128) with a size of 7×7 cm and had a subtended visual angle of 6.69° (horizontally and vertically) from a viewing distance of 60 cm.

A Dell computer with a 16-inch VGA display (frequency 60 Hz, resolution 1024×768) was used for stimulus presentation. The E-prime 2.0 software package (Psychology Software Tools, Pittsburgh, PA, USA) was used for response sampling.

2.3 Procedure and tasks

2.3.1 Masked priming task

Participants were instructed to respond to the geometric form of the target stimuli as quickly and accurately as possible by pressing the appropriately assigned key on a computer keyboard. An image of a circle or a diamond was assigned to the “f” key, and an image of an ellipsoid or a square was assigned to the “j” key. The reaction was counterbalanced across participants; that is, half the participants followed the aforementioned stimulus-response key assignment, and the remaining participants followed the opposite stimulus-response key assignment.

The sequence of each trial in the masked priming task is shown in Fig. 1 and is described as

follows: (1) a fixation cross appeared for 750 ms; (2) a forward mask (i.e., an image containing many randomly oriented lines) appeared for 200 ms; (3) the priming stimulus appeared for 33 ms; (4) a backward mask (i.e., another image containing many randomly oriented lines that differed from the forward mask) appeared for 33 ms; (5) the target stimulus appeared for 500 ms; (6) a blank screen appeared for 1000 ms. Participants were required to report their decision (i.e., press the appropriate key) within 1500 ms. The interval between trials varied randomly from 1000 to 1500 ms.

(Insert Figure 1 about here)

All participants were given 24 practice trials before the formal experiment began. The masked priming task followed and included four blocks of 168 total trials. The relationship between the prime and target allowed for two experimental conditions: congruent, for which the prime and target had same response, and incongruent, for which the prime and target had a different response. Within each block, half the trials were congruent, and the remaining trials were incongruent. The four geometric forms appeared equally often as primes and targets and were varied across trials to avoid repetition response priming effect.

2.3.2 Prime identification control task

To assess whether or not participants consciously perceived the prime, they participated in a task that provided a subjective measure of conscious awareness after finishing the masked priming task. For this measure, all participants were verbally asked whether they were aware of the primes that were presented before the targets. In addition, the participants performed an objective measure of prime identification. The prime identification task procedure was identical to the masked priming task in that participants were asked to respond to the geometric form of the primes with the same stimulus-response key assignment as was used for the priming task. However, response accuracy was stressed over response speed. Participants were required to make their best guess when they were unable to determine the form of the primes.

2.4 Statistical analysis

2.4.1 Reaction times and response errors

To minimize errors caused by incorrect and extreme values, incorrect and missed trials (17.52%) and reaction times (RTs) that deviated by more or less than three standard deviations (0.83%) were removed from further analysis. The mean RT of the correct responses and the mean error rates (ERs) were calculated for each participant and each experimental condition. Two-way repeated-measures analyses of variance (ANOVAs) were used to examine the mean RTs and ERs, with the within-subjects factor being response congruency (congruent vs. incongruent) and the between-subjects factor being expertise (athletes vs. non-athletes).

2.4.2 Identification rates

We used the statistic d' as a signal detection measure to assess prime visibility. Consistent with the work of Green and Swets (1966), the present study considered a correct response to the target stimulus on a congruent trial a hit and an erroneous response to the target stimulus on an incongruent trial a false alarm (Kiefer & Martens, 2010). The hit rates and false-alarm rates were calculated for each participant, and the identification rate d' was calculated from each participant's hit and false-alarm rates.

In order to obtain an objective measure of the ability to identify the geometric prime form presented between the two masks, one sample t -tests were performed to determine whether the identification performances of athletes and non-athletes were distributed around the level of chance, that is, at 50% (which is indicated by $d' = 0$). We then compared the identification rates (d') between athletes and non-athletes through independent t -tests. To rule out that any unconscious response priming effect observed among athletes correlated with prime visibility, Pearson's correlation between the identification rate d' and the size of the unconscious response priming effect was performed for the group of athletes.

3. Results

3.1 Reaction times and response errors

The results of a two-way repeated-measures ANOVA examining RTs revealed a significant main effect of response congruency ($F_{(1,49)} = 11.44$; $p = 0.001$; $\eta_p^2 = 0.19$). The interaction between expertise and response congruency was also significant ($F_{(1,49)} = 8.43$; $p = 0.006$; $\eta_p^2 = 0.15$). A simple effects analysis of the interaction showed that athletes responded faster on congruent trials than on incongruent trials (mean \pm standard error: congruent, 489.15 ± 9.75 ms; incongruent, 500.33 ± 8.99 ms; $p = 0.00$). By contrast, there was no significant difference in reaction times between congruent and incongruent trials for non-athletes (congruent, 500.56 ± 9.56 ms; incongruent, 501.41 ± 8.82 ms; $p = 0.734$). In addition, the main effect of expertise did not reach statistical significance ($F_{(1,49)} = 0.23$; $p = 0.633$; $\eta_p^2 = 0.01$) (Fig. 2).

(Insert Figure 2 about here)

An analogous two-way repeated-measures ANOVA on ERs revealed a significant main effect of response congruency ($F_{(1,49)} = 38.39$; $p = 0.00$; $\eta_p^2 = 0.44$). The interaction between expertise and response congruency was also significant ($F_{(1,49)} = 22.80$; $p = 0.00$; $\eta_p^2 = 0.32$). For response congruency, the simple effects analysis of the interaction showed that athletes committed fewer errors on congruent trials than on incongruent trials (congruent, $13.00\% \pm 1.59\%$; incongruent, $26.36\% \pm 2.08\%$; $p = 0.001$). By contrast, there was no significance difference in ERs between congruent and incongruent trials for non-athletes (congruent, $14.27\% \pm 1.56\%$; incongruent, $16.00\% \pm 2.04\%$; $p = 0.572$). For expertise, athletes committed more errors than non-athletes on incongruent trials (athletes, $26.36\% \pm 2.08\%$; non-athletes, $16.00\% \pm 2.04\%$; $p = 0.00$), but not on congruent trials (athletes, $13.00\% \pm 1.59\%$; non-athletes, $14.27\% \pm 1.56\%$; $p = 0.315$). However, the main effect of expertise did not reach significance ($F_{(1,49)} = 3.94$; $p = 0.053$; $\eta_p^2 = 0.07$) (Fig. 3).

(Insert Figure 3 about here)

3.2 Prime visibility

The signal detection analysis on the performance of participants to identify the masked primes indicated that for athletes d' was 0.14, which did not deviate significantly from zero ($t_{(24)} = 0.97$, $p = 0.341$). In addition, for non-athletes, d' was 0.06, which also did not differ significantly from zero ($t_{(25)} = 0.81$, $p = 0.425$). Furthermore, no significant difference was found between the d' values of athletes and non-athletes ($t_{(49)} = 0.48$, $p = 0.636$). These results indicated that neither athletes nor non-athletes could consciously perceive the masked primes.

The distribution of the identification rates d' (Kolmogorov-Smirnov = 0.14, $p = 0.20$) and the size of the unconscious response priming effect (Kolmogorov-Smirnov = 0.10, $p = 0.20$) for athletes were normal. For athletes, the identification rates d' and the size of the unconscious response priming effect did not correlate with each other ($r(25) = -0.19$, $p = 0.377$), suggesting that the unconscious response priming effect of the athletes was not the result of their awareness of the masked primes.

4. Discussion

Although unconscious executive control among athletes is reportedly better than that of non-athletes in the sports-specific domain, it has not been fully shown whether athletes also show superior unconscious executive control in the general domain. Thus, to determine whether motor expertise is associated with unconscious executive control in the general domain, we compared the performance on a masked priming task that used geometric forms as prime and target stimuli in a group of competitive table tennis players who had extensive motor expertise with that of a group of college students who had no specific motor expertise. Our primary results showed that athletes responded faster and committed fewer errors on trials in which the prime and target stimuli were congruent (i.e., required the same response) than on trials in which they were incongruent. By contrast, there was no significant difference in reaction times or errors rates

between congruent and incongruent trials for non-athletes.

Athletes showed a significant unconscious response priming effect, consistent with the results of a previous study that has shown that motor expertise promotes unconscious processing in the general cognitive domain (You et al., 2018). Schütz-Bosbach and Prinz (2007) have suggested that perceptual sensitivity is a prerequisite for unconscious processing. We selected geometric forms as prime and target stimuli because they are considered well-known to most people (Kiesel et al., 2009). Thus, we believed that both athletes and non-athletes would show high perceptual sensitivity to these geometric forms. However, our results showed that only athletes exhibited a significant unconscious response priming effect; the non-athletes did not. We speculate that this result is because the motor expertise possessed by athletes facilitates unconscious information processing. A characteristic of competitive sports is that they require rapid and changeable responses. Given the Olympic motto “faster, higher, and stronger” (Coubertin, 2008) incentive, competitive sports, especially open skills sports, have developed so that the movement speed of athletes and sports equipment exceeds the perception threshold of individuals most of time. For example, in table tennis, the ball speeds may be up to 144-180 km/h, and the contact time between the ball and the racket is only approximately 0.01 s (Bootsma & Van Wieringen, 1990). With such time pressure, the decisions made by competitive athletes are usually intuitive and without any explicit evaluation of the perceived information (Raab & Johnson, 2008; Williams & Ward, 2007). Table tennis is an open skills sport in which athletes are required to react in a dynamically changing environment, and likely because of their years of training, these athletes show more unconscious behaviors compared with non-athletes (Wang et al., 2013; Yu, Chan, Chau, & Fu, 2017). The masked priming paradigm used in present study closely replicated the time pressure of an open skills sport and was favorable for the performance of the athletes.

Compared with the number of words used as prime and target stimuli in previous studies (Martens, Ansorge, & Kiefer, 2011; Ulrich, Adams, & Kiefer, 2014), the number of geometric forms used in present study was small. In addition, each geometric shape had a unique physical feature. Participants can store the geometric forms and their corresponding reactions in their

working memory, and then form a stimulus-reaction connection between the stimuli and reactions (Kiesel, Kunde, Poh, & Hoffmann, 2006; P. Wang, Huo, & Wang, 2012). The present results indicated that the performance of athletes was significantly influenced by the presentation of the geometric forms despite their perception being unconscious, whereas the performance of non-athletes was not affected by the presentation of geometric forms. This result may be because athletes established an unconscious association between the stimuli and motor responses during the practice experiments, whereas the non-athletes did not. Thus, the motor reactions of the athletes would be facilitated or disrupted by the unconsciously perceived primes. In other words, the unconsciously perceived geometric shapes could have activated the previously established stimulus-response assignment and triggered a motor response when the prime and target were congruent. The response to the target would be facilitated because it was pre-activated by the prime. By contrast, when the prime and target stimuli required a different response (i.e., were incongruent), the response to the target would have been interfered because the pre-activated response was inconsistent with the required target response. Athletes need to timely inhibit the incorrect motor response tendency, retrieving the appropriate stimulus-response assignment. Hence, athletes responded faster and committed fewer errors on congruent trials than on incongruent trials. Although there was a tendency for a similar result among non-athletes, the difference was not statistically significant. The results indicated, to some extent, that non-athletes appeared to sense a conflict between an incongruent prime and target, but compared with athletes, the conflict felt by non-athletes was substantially smaller. Owing to lack of a stable connection between the stimuli and motor reactions in non-athletes, the geometric forms presented unconsciously did not influence their performance. Thus, no significant unconscious response priming effect was found among non-athletes. This finding explains why the ERs among athletes were higher than those among non-athletes on incongruent trials.

Our results showed that non-athletes exhibited no significant unconscious response priming effect. However, this finding was inconsistent with that of a previous study (Ulrich & Kiefer, 2016). To study the neural signature of the unconscious response priming effect, Ulrich and

Kiefer (2016) recruited college students to participate in a masked priming task that also used geometric forms, their results showed that the participants exhibited a significant unconscious response priming effect. We speculate that the lack of sufficient practice for the college students in our study may have led to the different results. Previous studies have suggested that long periods of practice are required for unconscious or implicit learning (Lewicki, Czyzewska, & Hoffman, 1987; Wulf & Schmidt, 1997). In the present study, participants were allowed 24 practice trials, whereas in the Ulrich and Kiefer (2016) study, participants were given up to 32 practice trials. Given the more limited practice allowed in our study, athletes could master the rules faster and better than non-athletes and then could establish a stable unconscious connection between the stimuli and motor response. By contrast, this connection was not stable in non-athletes and had not reached an automatic level. Thus, the stimuli presented below the threshold of consciousness had no influence on the performance of non-athletes.

Our findings, together with the results from previous studies, not only add further evidence to support that expertise is an important determinant of unconscious processing but also provide preliminary evidence that, compared with non-athletes, athletes exhibit superior unconscious processing of executive control in the general domain. This finding suggests that the influence of motor expertise on unconscious executive control is transferable from the sports-specific domain to the general cognitive domain.

5. Limitations

The present study had some limitations. First, we did not detect a significant unconscious response priming effect among non-athletes in the masked priming task; as suggested above, this result may have been due to a lack of practice on the task prior to the formal experiment. Allowing more practice should be a consideration for future studies. Second, the sample size of participants, especially female participants, in the present study was small. To reduce the effect of individual differences, the number of participants should be increased in future studies. Third, the athletes played table tennis, which is an open skills sport. In order to better identify the

facilitation of motor expertise on unconscious executive control in the general cognitive domain, athletes who play closed skills sports should also be recruited in future studies. Finally, although the present study described the influence of motor expertise on the unconscious executive control of the general domain on a behavior level, the neural signature of this phenomenon remains unclear and warrants future exploration.

6. Conclusions

The findings of our study provide evidence that motor expertise facilitates the unconscious processing of geometric forms, indicating that the influence of motor expertise on unconscious executive control is not just sports-specific but can be transferred to the general cognitive domain.

Figure 1

The masked priming task

Trial sequence of the masked priming task.

Figure 2

Mean reaction times for trials with correct responses in the masked priming task for athletes and non-athletes.

The vertical bars represent mean reaction times as a function of response congruency and expertise. White bars represent reaction times of congruent responses, and black bars represent reaction times of incongruent responses. Error bars indicate standard error of mean; *** $p < 0.001$ for the indicated comparison.

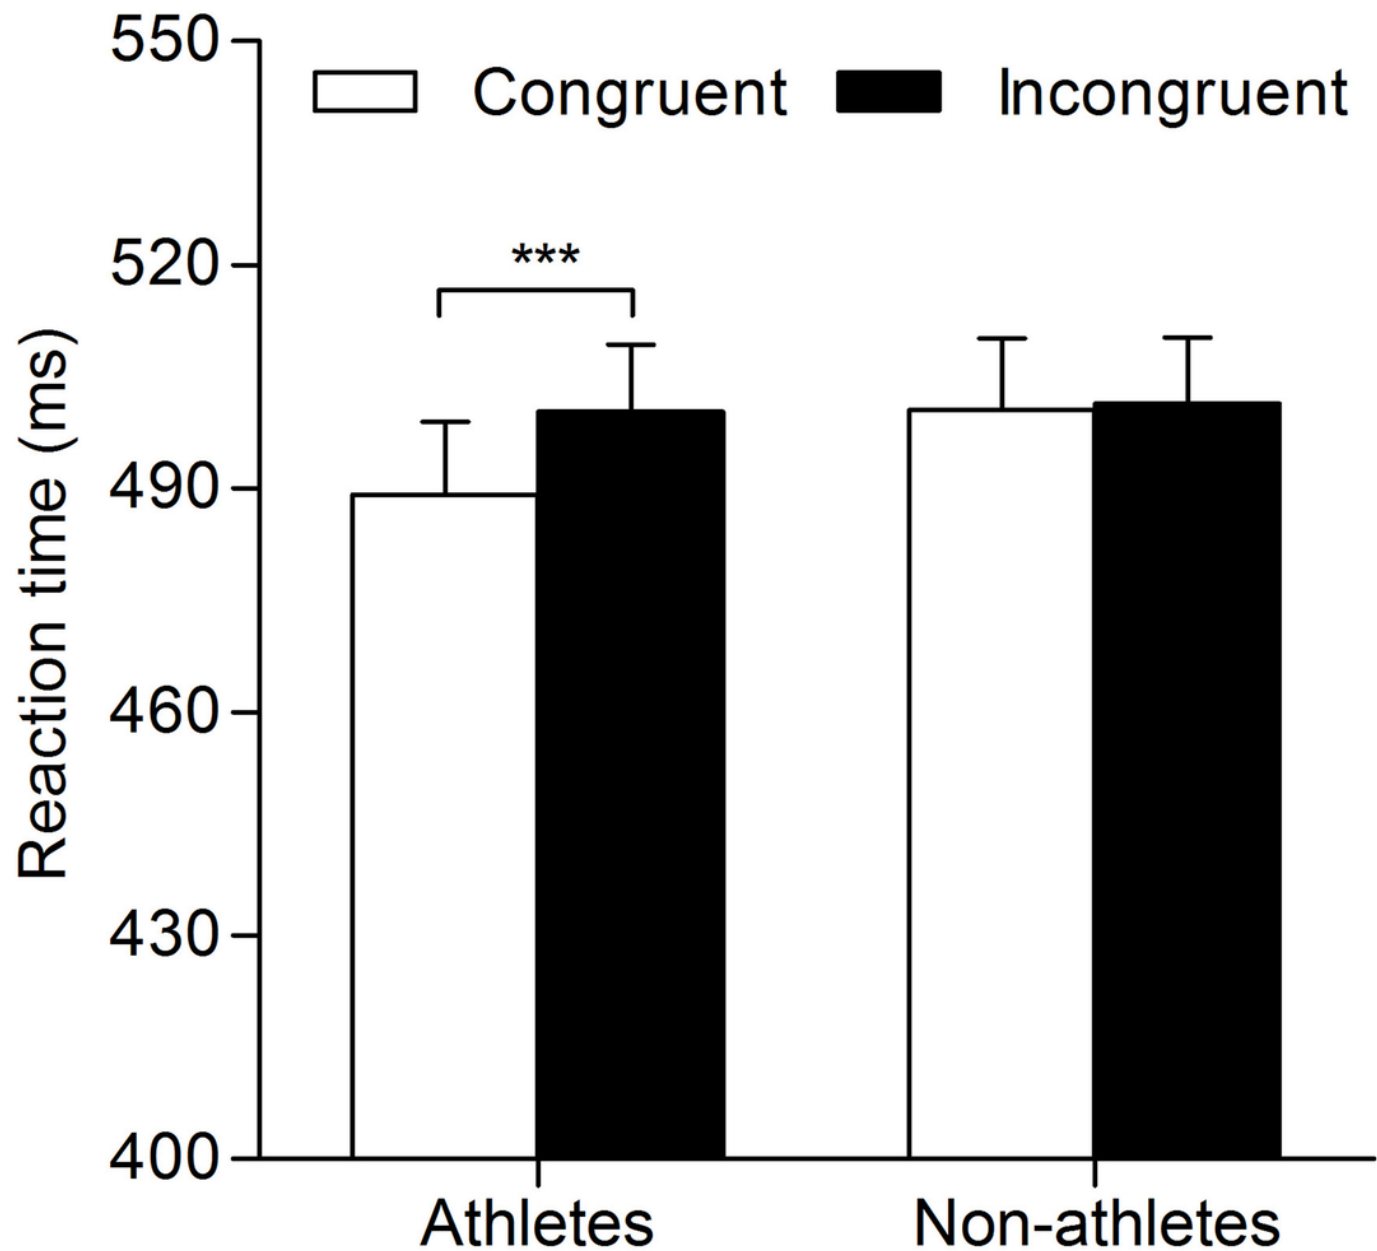

Figure 3

Mean error rates for athletes and non-athletes in the masked priming task for athletes and non-athletes.

The vertical bars represent mean error rates as a function of response congruency and expertise. White bars represent error rates of congruent responses, and black bars represent error rates of incongruent responses. Error bars indicate standard error of mean; $**p < 0.01$, $***p < 0.001$ for the indicated comparisons.
