The question of whether animals have some sort of self-awareness is a topic of great interest and subject of continued debate. A necessary precondition for self-awareness is the ability to visually discriminate the self from others, which has traditionally been investigated through mirror self-recognition. Although great apes generally pass mirror self recognition tasks, the interpretation of these results has remained controversial. The aim of this study was to investigate how bonobos (*Pan paniscus*) respond to different types of images of themselves and others. In the first part of the experiment, we presented mirror-naïve subjects with three representations of themselves (contingent mirror image, contingent video footage, non-contingent video footage) and two representations of others (video footage of known and unknown conspecifics). We compared responses using a 'looking-time' paradigm, based on the finding that primates generally prefer to look at novel social stimuli. We found that subjects paid little attention to contingent images of themselves and while interest in footage of known individuals was a little higher, subjects were most interested in non-contingent images of themselves and of unfamiliar individuals. In the second part of the experiment, we provided subjects with three months of *ad libitum* mirror access, after which subjects were retested with the same non-contingent video footage of themselves and of unknown conspecifics. We found that extensive experience with their own mirror-image significantly reduced interest in the non-contingent footage of self, but not in the footage of unknown individuals. We concluded that, when provided with extended mirror experience, bonobos may form stable visual mental representations of themselves, which enable them to recognise themselves in non-contingent video footage. We discuss the implications of these findings in relation to the on-going debate on self-recognition in animals.

## 11 **Abstract**

12 The question of whether animals have some sort of self-awareness is a topic of great interest and  
13 subject of continued debate. A necessary precondition for self-awareness is the ability to visually  
14 discriminate the self from others, which has traditionally been investigating through mirror self-  
15 recognition. Although great apes generally pass mirror self recognition tasks, the interpretation  
16 of these results has remained controversial. The aim of this study was to investigate how  
17 bonobos (*Pan paniscus*) respond to different types of images of themselves and others. In the  
18 first part of the experiment, we presented mirror-naïve subjects with three representations of  
19 themselves (contingent mirror image, contingent video footage, non-contingent video footage)  
20 and two representations of others (video footage of known and unknown conspecifics). We  
21 compared responses using a ‘looking-time’ paradigm, based on the finding that primates  
22 generally prefer to look at novel social stimuli. We found that subjects paid little attention to  
23 contingent images of themselves and while interest in footage of known individuals was a little  
24 higher, subjects were most interested in non-contingent images of themselves and of unfamiliar  
25 individuals. In the second part of the experiment, we provided subjects with three months of *ad*  
26 *libitum* mirror access, after which subjects were retested with the same non-contingent video  
27 footage of themselves and of unknown conspecifics. We found that extensive experience with  
28 their own mirror-image significantly reduced interest in the non-contingent footage of self, but  
29 not in the footage of unknown individuals. We concluded that, when provided with extended  
30 mirror experience, bonobos may form stable visual mental representations of themselves, which  
31 enable them to recognise themselves in non-contingent video footage. We discuss the  
32 implications of these findings in relation to the on-going debate on self-recognition in animals.

33

## 34 **Introduction**

35 A fundamental question in comparative cognition is whether, or to what degree, non-human  
36 animals have something akin to human self-awareness, that is, whether they can recognise  
37 themselves as separate from others and the environment and whether they have some  
38 understanding of their own mental states. It is generally accepted that any form of self-awareness  
39 arguably presupposes self-recognition, which is empirically easier to address. Since the 1970s  
40 mirrors have been used as the main method of testing self-recognition, with two basic types of  
41 data collected. These studies have relied either on both the spontaneous and sequential  
42 appearance of social, exploratory, contingent and self-directed behaviours (Swartz, Sarauw &  
43 Evans, 1999) and the self-directed behaviour in response to inconspicuous marking of a body  
44 part, not visible without the aid of a mirror (the mirror-mark test; Gallup (1970)) or on one or the  
45 other.

46

47 Gallup's (1970) research on chimpanzees and macaques was pioneering, and has been followed  
48 by studies on a range of other primate species, including humans (Amsterdam, 1972),  
49 chimpanzees (Gallup, 1970; Lethmate & Dücker, 1973; Suárez & Gallup, 1981; Calhoun &  
50 Thompson, 1988; Swartz & Evans, 1991; Lin, Bard & Anderson, 1992; Povinelli et al., 1993),  
51 bonobos (Hyatt & Hopkins, 1994; Westergaard & Hyatt, 1994; Walraven, Van Elsacker &  
52 Verheyen, 1995), gorillas (Suárez & Gallup, 1981; Ledbetter & Basen, 1982; Posada & Colell,  
53 2007), orang-utans (Lethmate & Dücker, 1973; Suárez & Gallup, 1981), lesser apes (Lethmate &  
54 Dücker, 1973; Inoue-Nakamura, 1997; Suddendorf & Collier-Baker, 2009), monkeys (Lethmate  
55 & Dücker, 1973; Inoue-Nakamura, 1997), and prosimians (Inoue-Nakamura, 1997) (see  
56 Anderson, 1984 for review in primates).

57

58 Within the non-human primates, all great apes appear to be capable of mirror self-recognition  
59 (see Swartz, Sarauw & Evans, 1999 for review). In bonobos, for example, there is evidence of  
60 spontaneous self-recognition in mirrors (Hyatt & Hopkins, 1994; Westergaard & Hyatt, 1994;  
61 Walraven, Van Elsacker & Verheyen, 1995), due to mirror-guided self-directed behaviour (e.g.  
62 picking the teeth or eyes), in some instances from first exposure (Walraven, Van Elsacker &  
63 Verheyen, 1995), although we are not aware of any reports of studies using the ‘mirror-mark’  
64 test on bonobos. In contrast, lesser apes (*Hylobates lar*, *H moloch*, *H agilis*, *Nomascus*  
65 *leucogenys* and *Symphalangus syndactylus*) and monkeys (*Macaca silenus*, *Mandrillus sphinx*,  
66 *Papio hamadryas*, *Ateles sp*, *Cebus apella*) have consistently failed the ‘mirror-mark’ test  
67 (Lethmate & Dücker, 1973; Suddendorf & Collier-Baker, 2009). This conclusion is further  
68 corroborated by the absence of spontaneous self-directed behaviours in non-ape primates  
69 (*Hylobytes lar*; *Macaca spp.*, *Cebus apella*, *Saimiri sciureus*, *Saguinus oedipus*, *Lemur catta*;  
70 Inoue-Nakamura, 1997; but see Heschl & Fuchsichler for tentative evidence of mirror self-  
71 recognition in a lesser ape).

72

73 Mirror experiments have also been conducted with non-primate species bringing to light  
74 somewhat controversial evidence (see Gallup & Anderson, 2018 for a critical view) in bottlenose  
75 dolphins (Marten & Psarakos, 1994; Reiss & Marino, 2001), Asian elephants (Plotnik, De Waal  
76 & Reiss, 2006), and even manta rays, the biggest brained of all fish (Ari & D’Agostino, 2016),  
77 suggesting that mirror self-recognition may have more to do with large brains in general,  
78 regardless of phylogenetic relatedness. Meanwhile, small-brained species typically fail mirror  
79 self-recognition tasks (e.g. great tits, (Kraft et al., 2017); cichlid fish (Hotta, Komiyama &

80 Kohda, 2018), although, there is positive evidence from Eurasian magpies (Prior, Schwarz &  
81 Güntürkün, 2008; but see Anderson & Gallup, 2015 for a critical view of these results) and  
82 Clark's nutcrackers (Clary & Kelly, 2016). However, the giant panda's failure of mirror self-  
83 recognition (Ma et al., 2015) seems to suggest that large brains alone might not be enough  
84 suggesting that mirror self-recognition might further be linked to social variables (Gallup, 1998;  
85 Prior, Schwarz & Güntürkün, 2008).

86

87 In humans and great apes, the capacity to recognise one's self in a mirror emerges gradually with  
88 appropriate experience. In western human cultures, the capacity to carry out self directed  
89 behaviours in front of a mirror usually appears from 15-18 months of age and is fully expressed  
90 by 24 months (e.g. Amsterdam, 1972; Lewis & Brooks-Gunn, 1979; but see Keller et al., 2004,  
91 2005; Kärtner et al., 2012 for evidence of delayed mirror self-recognition emergence in other  
92 cultures). In chimpanzees, early reactions to mirrors are similar in kind and latency to those  
93 observed in human children, but the behaviour does not emerge before 24 months (Lin, Bard &  
94 Anderson, 1992) and is robustly present only from around 5 years (Swartz, Sarauw & Evans,  
95 1999) with some individuals never developing the capacity (e.g. Swartz & Evans, 1991;  
96 Povinelli et al., 1993; Walraven, Van Elsacker & Verheyen, 1995). Behaviours typically  
97 observed by mirror-naïve animals are, first, social behaviours directed at the mirror (e.g.  
98 threatening, vocalising etc. (Gallup, 1970)), followed by exploratory behaviours (e.g. reaching or  
99 looking behind the mirror), exploration of the contingency between the mirror-image and the  
100 subject's body, and, finally, exploration of body parts that are usually visually inaccessible, such  
101 as the teeth, eyes or genital regions (Swartz, Sarauw & Evans, 1999).

102

103 There is much controversy around how evidence of mirror self-recognition should be interpreted.  
104 On one end of the spectrum is the interpretation that positive evidence is an indicator of self  
105 awareness (Inoue-Nakamura, 1997; Gallup, 1998; Swartz, Sarauw & Evans, 1999; Plotnik, De  
106 Waal & Reiss, 2006) or even for a self-concept, defined by Gallup (1998, p. 240) as "...a sense  
107 of continuity, a sense of personal agency and a sense of identity". At the other end, reactions  
108 towards administered marks have been interpreted as mere artefacts of experimental  
109 manipulations (Heyes, 1994, 1995, 1996). More intermediate position state that such behaviour  
110 qualifies as evidence for self-perception, that is, recognising one's own appearance (Nielsen,  
111 Suddendorf & Slaughter, 2006) or a basic understanding of one's own body as a separate entity  
112 from the surrounding world ('body concept'). The 'body-concept' hypothesis has been  
113 investigated in developing children, with the conclusion that objective self-awareness emerges in  
114 the second year of life, correlated with passing the mirror-mark test, which suggests that the two  
115 capacities are linked (Moore et al., 2007). The notion of a 'body concept' is also key to an  
116 alternative hypothesis to self-recognition, which is that subjects simply engage in some form of  
117 kinaesthetic-visual matching as they identify the contingency between the kinaesthetic sense of  
118 their body and its movements and the objective visual image as provided by the mirror (Mitchell,  
119 1993, 1997).

120

121 Several studies on children have tested the effect of contingency cues on self-recognition by  
122 presenting non-contingent cues, usually delayed videos or simply photographs. While some  
123 claim that children are able to identify themselves by ages 18-24 months, regardless of  
124 contingency cues (Lewis & Brooks-Gunn, 1979), others have shown not only a clear  
125 developmental trend of self-recognition from non-contingent images between the ages of two

126 and four, but also a significant delay compared to the emergence of mirror self-recognition  
127 (Povinelli, Landau & Perilloux, 1996). Of course, self-recognition from delayed, non-contingent  
128 self-images presupposes that individuals, human or non-human, acquire sufficient mirror-  
129 exposure to derive and develop a visual mental representation of their own appearance. As  
130 previously mentioned, in non-human animals the first response to their mirror-image is to treat it  
131 as another conspecific (Swartz, Sarauw & Evans, 1999).

132

133 Given their phylogenetic closeness to both humans and chimpanzees and based on their capacity  
134 for mirror self-recognition (Hyatt & Hopkins, 1994; Westergaard & Hyatt, 1994; Walraven, Van  
135 Elsacker & Verheyen, 1995) (demonstrating their ability to form a self-image based on  
136 kinaesthetic-visual matching) it is reasonable to suppose that, with extended mirror experience,  
137 bonobos might be capable of developing full visual self-images, with an understanding of their  
138 physical appearance. If this is the case, a visual mental representation may be formed from  
139 exposure to one's mirror image and potentially stored in memory. The aim of this study was to  
140 address how bonobos respond to different visual images of self and others and to investigate how  
141 mirror exposure influenced perception of self-images when contingency cues are absent. We  
142 exposed subjects to different visual representations of themselves and known and unknown  
143 others and considered subjects' differing responses between conditions. We hypothesised that  
144 bonobos may not have an a-priori ability to recognise themselves, particularly in the absence of  
145 kinaesthetic-visual matching opportunities, but that they have the ability to develop a visual  
146 mental representation of self, if given sufficient visual experience. To this end, we first exposed  
147 subjects to different depictions of the self and others. Two years later, following a 3-month  
148 period of *ad libitum* access to a mirror we exposed the same subjects again to key depictions of

149 the self and others. We hypothesized that prolonged mirror-exposure would provide subjects  
150 with crucial perceptual experience regarding their own physical appearance, which subjects  
151 might use to develop a visual mental representation of self, enabling them to recognise non-  
152 contingent representations of themselves, without the help of kinaesthetic feedback.

153

154 We assessed interest in the different stimuli by comparing differences in looking times. This is  
155 based on the more general finding that both human and nonhuman primates generally spend  
156 more time looking at novel than familiar stimuli (e.g. patterns: (Fantz, 1964; Gunderson &  
157 Sackett, 1984; Gunderson & Swartz, 1985); objects: (Bachevalier, Brickson & Hagger, 1993;  
158 Pascalis & Bachevalier, 1998); conspecific faces: (Pascalis & Bachevalier, 1998; Gothard,  
159 Erickson & Amaral, 2004; Gothard, Brooks & Peterson, 2009).) As a general pattern, in tasks  
160 relating to face recognition of conspecifics, all species tested show a visual bias for novelty  
161 (Pascalis & de Schonen, 1994; Pascalis & Bachevalier, 1998; Gothard, Erickson & Amaral,  
162 2004; Gothard, Brooks & Peterson, 2009; but see Winters, Dubuc & Higham, 2015 for an  
163 overview of issues and controversy around the looking-time paradigm.), while a visual bias for  
164 familiar stimuli has only been observed in studies comparing conspecific vs. (novel) hetero-  
165 specific faces (Fujita, 1987; Demaria & Thierry, 1988). Familiar stimuli were also preferred in a  
166 reaching paradigm for familiar vs. novel hidden objects (Shinsky & Munakata, 2005).  
167 Furthermore, during visual processing and formation of mental representations in human infants  
168 a bias for a familiar stimulus precedes an inevitable and consistent bias for a novel stimulus  
169 (Roder, Bushnell & Sasseville, 2000).

170

171 We hypothesize that if bonobos show more interest (i.e., look longer) in novel than familiar

172 stimuli, similarly to other tested primates (Gunderson & Sackett, 1984; Bachevalier, Brickson &  
173 Hagger, 1993; Pascalis & de Schonen, 1994), then any footage perceived as unfamiliar should  
174 cause longer looking times than footage perceived as familiar. In particular, if subjects failed to  
175 recognise visual representations of themselves, then these should cause longer looking time than,  
176 for instance, footage of familiar group members.

177

## 178 **Methods**

### 179 **Study site & subjects**

180 The study was carried out at La Vallée des Singes Primate Park in Romagne (France) with a  
181 group of bonobos (2014: N=17; 2016: N=20; Table 1) housed in an indoor enclosure (400m<sup>2</sup>)  
182 with access to two outdoor wooded islands (11,500m<sup>2</sup>). Experiments were carried out from  
183 January to July 2014 and February to July 2016.

184

185 Eight subjects (4 males; 4 females see Table 1) participated in all trials, which involved a visual  
186 bias task with sequential stimulus presentation, a paradigm originally developed in the late 1950s  
187 for research with pre-verbal human infants (e.g. Fantz, 1963; Winters, Dubuc & Higham, 2015).

188

189 Prior to testing, individuals were exposed to the equipment during one week to minimise any  
190 potential effects of novelty. Videos stimuli were then presented by means of an APPLE iPad  
191 placed behind a transparent Acrylic panel (Fig. 1a) to which a PANASONIC HC-V100 full HD  
192 camera was fixed in order to record the subject's reaction face-on. The mirror stimulus was

193 presented by means of a one-way mirror (25 x 30 cm) attached behind the same panel (Fig. 1b  
194 and c).

195

## 196 **Part 1 - Before mirror exposure**

197 The first part of the experiment was carried out in 2014 with N=8 subjects who had no known  
198 prior experience with mirrors. The experiment comprised five experimental conditions presented  
199 to all subjects in the following order: (1) contingent video footage of self (live feedback of self  
200 visible on iPad: *C self*); (2) contingent mirror image of self (live depiction of self visible on one-  
201 way mirror: *mirror*); (3) non-contingent video footage of self (previously recorded video footage  
202 of self visible on iPad: *NC self*); (4) footage of known group member (previously recorded video  
203 footage of other group member visible on iPad: *known*); (5) footage of unknown conspecific  
204 (previously recorded video footage of unfamiliar conspecific visible on iPad: *unknown*) (see  
205 Tables S1 and S2). Footage for '*NC self*' and '*known*' were recorded during the '*mirror*' and '*C*  
206 *self*' conditions. Footage for '*unknown*' (N=2 males; N=1 female) were recorded at the 'Lola ya  
207 Bonobo' Sanctuary in the Democratic Republic of the Congo (see ESM 2 and 3 for sample  
208 footage). In both the '*known*' and '*unknown*' conditions, the footage showed generally inactive  
209 individuals glancing at the camera from time to time. Footage for stimulus presentation was  
210 selected at random, resulting in N=6 same-sex pairs and N=2 opposite-sex pairs for the '*known*'  
211 condition and N=4 same-sex and N=4 opposite-sex pairs for the '*unknown*' condition.

212

213 Each subject was presented with each of the five conditions once only and in the same sequential  
214 order over an eight-month period (see Table S2). All video stimuli were presented very briefly,

215 for total of 30 seconds, starting with the first glance from the subject towards the stimulus. A  
216 trial was terminated after 30s or as soon as a subject upped and left.

217

218 We are aware of the fact that fixed order stimulus presentation designs carry the disadvantage of  
219 potentially creating systematic cross-condition dependencies. Any eventual differences in  
220 behavioural responses could therefore be explained in terms of behavioural  
221 habituation/sensitisation to some unknown aspects of the experiment (e.g. iPad) rather than  
222 stimulus properties per se. Despite this well-known disadvantage, we opted for fixed order  
223 stimulus presentation because we were interested in eventual changes of attention due to  
224 prolonged exposure to a mirror. It was therefore essential that all subjects entered the experiment  
225 with the exact same stimulus history before and after mirror exposure. We consider it unlikely  
226 that this design could explain differences across conditions, mainly because stimulus exposure  
227 was very short (30s) and time lapse across presentations was generally very large (Mean = 43.3  
228 days / Median = 38.5 days RANGE: 0-95).

229

230 Stimulus presentation was carried out whenever a subject was alone in one of the indoor cages  
231 and at a suitable orientation and distance from the corridor (0.3-2.0 m). The subject was tested  
232 only if inactive (resting and observing) and exposed to one of two portable devices, an iPad or a  
233 one-way mirror, each with a camera mounted to record looking responses (fig. 1).

234

235 We measured looking time during stimulus presentation as a proxy for interest, coded post-hoc  
236 from the video recordings. Coding was blind insofar as all videos were randomly labelled so that

237 the coder was unable to infer the experimental condition. Videos were analysed frame-by-frame  
238 with MPEG Streamclip 1.9.2.

239

240 Eight of 17 adult group members were tested and analysed in this study (see Table 1). Regarding  
241 the remaining individuals (N=9): One adult male (BO) participated in all experimental conditions  
242 but had to be excluded due to poor video quality, which prevented accurate coding. One adult  
243 female (LY) had to be excluded because she only participated in two conditions. Two individuals  
244 (NK and LUE) had to be excluded because they were too close to the camera, which prevented  
245 reliable coding of looking time. Finally, we were unable to test the remaining adult females  
246 (DNL and UK). The dependant infants and juveniles (LO, MO and KLS) were not tested.

247

## 248 **Part 2 - After mirror exposure**

249 Fifteen months after the first part of the experiment was completed (i.e., from Nov 2015  
250 onwards), subjects were provided with prolonged access to a mirror to gain extended experience  
251 with mirror reflections of themselves. A mirror (45 x 115 cm) was placed in front of a resting  
252 platform of the indoor enclosure allowing *ad libitum* access over a period of three months (i.e.,  
253 from Nov 2015 to Feb 2016). At this time of year, the group was kept inside due to cold weather  
254 conditions and the park was closed to the public.

255

256 In order to test the effect of mirror experience on the subjects' perception of their own non-  
257 contingent image compared to footage of an unknown individual, all individuals that had  
258 participated in part 1 (N=8) were retested with two identical stimuli from part 1, specifically,  
259 non-contingent video footage of self (*NC self*) and video footage of unknown conspecifics

260 (*unknown*), in order to draw a comparison between the results before and after mirror exposure.  
261 Stimulus presentation began 10 - 20 days after removal of the mirror. All aspects of presentation  
262 were identical to part 1. The time lapse between the first and second stimulus presentation for a  
263 given subject and condition was held constant for each subject averaging at approximately 22  
264 months (see Table S2).

265

## 266 **Statistical analyses**

267 In a first analysis, prior to the 3-month mirror exposure, we modelled looking time with a linear  
268 mixed model (LMM), with looking time as the response variable and experimental condition as  
269 the main predictor variable. We included subject ID as random intercept. We added age as  
270 control predictor to account for the possibility that younger individuals might show more  
271 interested than older individuals (Westergaard & Hyatt, 1994; Walraven, Van Elsacker &  
272 Verheyen, 1995). Looking time and age were square root transformed to achieve homogenous  
273 and approximately normally distributed residuals. We tested this full model against an informed  
274 null model (which included only age as predictor and subject ID as random intercept) with a  
275 likelihood ratio test (LRT, Dobson, 2002). Note that this comparison is equivalent to more  
276 traditional p-value significance testing of ‘experimental condition’ (models with vs. without  
277 experimental condition).

278

279 Post hoc diagnostics were implemented in order to test the stability of the model. This entailed  
280 running the full model eight times, each time removing data of one of the eight individuals. This  
281 permitted us to verify whether one of the individuals was influential with respect to the

282 interpretation of our model results. Results of this procedure indicated stable model results, such  
283 that exclusion of any one individual did not change the conclusions of our analysis.

284

285 In a second analysis, we tested how looking time was affected by the interaction between  
286 stimulus type (self vs. unknown, i.e., self Y/N) and prolonged mirror exposure (non-exposed vs.  
287 exposed, i.e., exposed Y/N) using a LMM. Once again, we controlled for age, which was  
288 included in the respective null model, and we implemented post-hoc diagnostics, testing the  
289 stability of the model. Again, diagnostics results indicated stable model results.

290

291 Statistical analyses were carried out with R v. 3.1.2 and lme4 v. 1.1-11 (R Core Team, 2014;  
292 Bates et al., 2015). The data that support the findings of this study are available in the electronic  
293 supplementary material (ESM 4).

294

## 295 **Compliance with ethical standards**

296 Ethical approval: All applicable international, national, and/or institutional guidelines for the  
297 care and use of animals were followed. This experimental study was authorised and given ethical  
298 approval by the “La Vallée des Singes” scientific coordinator and zoological director. Trials  
299 were carried out opportunistically when and where subjects felt so inclined. The study was inline  
300 with the ARRIVE guidelines and recommendations from the EAZA and the AFdPZ code of  
301 ethics.

302

## 303 Results

304 The first part of the experiment consisted of exposing all subjects to different motion images of  
305 themselves, of other group members, or of unfamiliar conspecifics (see Table S2). The results of  
306 the model indicate that looking time was affected by experimental condition (LRT,  $\chi^2 = 25.87$ ,  
307 d.f. = 4,  $P < 0.001$ ; Fig. 2; Table 2).

308

309 The median looking time in both *C self* and *mirror* conditions was relatively low, standing just  
310 under five seconds (4.6s and 4.5s, respectively, medians calculated from raw data), whereas for  
311 the *NC self* and *unknown* conditions median looking time was approximately four to five times  
312 higher (22.1s and 18.1s, respectively). Median looking time for the *known* condition, however,  
313 lay in between (11.1s).

314

315 If we take looking time as an indicator of interest, these results indicate that subjects seemed to  
316 show relatively little interest in the contingent images of themselves (both on the iPad and the  
317 mirror) but showed more interest in non-contingent images of themselves and of unfamiliar  
318 individuals. If we agree that individuals show more interest (as measured by looking time) in  
319 novelty, then these results indicate that subjects did not treat the contingent images of themselves  
320 (*C self* and *mirror*) as novel but more we would have predicted for familiar images. Subjects did,  
321 however, show a lot of interest in the non-contingent images of themselves and the images  
322 unfamiliar individuals. A possible explanation for this discrepancy might be quite simple. When  
323 presented with the stimuli, exposure was very short (30s) and subjects did not move or interact  
324 with the images but generally just looked at them, as a result the contingent images of  
325 themselves (live representations) did not move either in comparison to the non-contingent

326 images of themselves, other known and unknown individuals. They might thus have been  
327 simply more interested in images of moving individuals than the relatively ‘still’ images.

328

329 In a second part, we therefore provided subjects with three months of *ad libitum* mirror access to  
330 test whether prolonged mirror experience with the opportunity to interact freely with their  
331 mirror-image would influence the way they perceived the delayed video footage of themselves.

332 Following this treatment and almost two years after the previous trials, subjects were retested  
333 with non-contingent footage of themselves (*NC self*) and of an unknown conspecific (*unknown*).

334 The full model was significantly different from the null model (LRT,  $\chi^2=18.06$ , d.f.=3,  $P<0.001$ ;  
335 Fig. 3, Table 3), indicating that looking time differed as a function of mirror-exposure, stimulus

336 identity, and their interaction. The interaction effect was close to significance (LRT,  $\chi^2=3.61$ ,

337  $df=1$ ,  $P=0.057$ ), indicating that interest as measured by looking time was substantially lower in

338 the *NC self* condition after the three-month mirror-exposure than before (median 22.1s vs. 7.4s),

339 which was not the case for the *unknown* condition (18.2s vs. 18.5s).

340

341 These results indicate that the prolonged mirror exposure modified subject interest in their non-

342 contingent self-images but not their interest in the images of unfamiliar individuals. Indeed, our

343 subjects were still very interested in the images of unfamiliar individuals but their interest in

344 their own delayed images decreased significantly. We are confident that the decrease of interest

345 for the *NC self* cannot simply be explained in terms of habituation to the stimuli given the fact

346 that the stimulus was presented once for 30s, 22 months prior to the second 30s presentation.

347 Furthermore, if that was the case then we should observe a similar pattern for the unknown

348 individual image. In conclusion, the exposure to the mirror seems to have allowed our subject to

349 learn something about their own physical appearance that in consequence led them to treat the  
350 delayed image of themselves as less novel than images of unfamiliar individuals.

## 351 **Discussion**

352 In this study we were interested in how mirror-naïve bonobos responded to different contingent  
353 live and non-contingent delayed images of themselves, as well as of known and unknown  
354 individuals, and how prolonged mirror-exposure influenced the response to non-contingent video  
355 footage of self. To address this, we carried out a two-part experiment during which subjects  
356 watched motion images of bonobos, depicting either themselves or another individual. In the first  
357 part of the experiment, subject response to three types of motion self-images (mirror reflection,  
358 contingent video feedback and non-contingent video footage) was compared with response to  
359 video footage of familiar and unfamiliar conspecifics. Results revealed low interest (as assessed  
360 by looking time) in the mirror condition and in contingent footage of the self. In contrast, interest  
361 was high in both non-contingent footage of self and footage of unfamiliar individuals while  
362 interest for footage of known individuals lay in between.

363

364 We draw the following tentative conclusions from these patterns. First, given that to the best of  
365 our knowledge the subjects were mirror-naïve and that human and nonhuman primates generally  
366 show more interest in novel than familiar stimuli, including faces (Pascalis & de Schonen, 1994;  
367 Pascalis & Bachevalier, 1998; Gothard, Erickson & Amaral, 2004; Dufour, Pascalis & Petit,  
368 2006; Gothard, Brooks & Peterson, 2009) we would have predicted high interest in all but the  
369 *known* condition. However, this is not what was observed as subjects showed surprisingly little  
370 interest in the *C self* and *mirror* conditions while, as predicted, they showed high interest in the

371 *NC self* and *unknown* conditions. Given these contrasting findings, several interpretations are  
372 required. First, a reasonable interpretation regarding the high interest for the *NC self* and  
373 *unknown* conditions is that the non-contingent footage of self (*NC self*) was not recognised as a  
374 representation of self, but as an unfamiliar individual and hence elicited equal interest.  
375 Supporting this first conclusion is the fact that subject interest in familiar conspecifics was  
376 somewhat intermediate, indicating that the high interest in the *NC self* and *unknown* conditions  
377 was not simply due to observing others through the novel medium of a video screen.  
378  
379 More difficult to explain is the low interest elicited by the two contingent self-images (*C self* and  
380 *mirror*). We would have expected both to elicit high interest due to the novelty and unfamiliarity  
381 of the perceived individual (self). We suggest that that it is the synchrony of the contingent  
382 images that elicits little interest in comparison to the asynchrony of the non-contingent footage.  
383 More explicitly, while there are few to no times when animals experience complete synchrony  
384 with an image, be it of themselves or of another, the reality is that when sitting looking at the  
385 synchronous image, the depicted individual is merely sitting and “looking back” whereas in a  
386 non-contingent and thus non-synchronous image, the depicted individual might seem more  
387 active, sitting and looking around, observing its environment, seemingly looking back at the  
388 subject and perhaps moving a little while the subject itself is not. Another suggestion, although  
389 less likely in our opinion, might be that subjects were already somewhat familiar with seeing  
390 their own reflection, in windows and water surfaces, providing them with sufficient contingency  
391 cues to recognise themselves in such reflections. Such self-images would not, however, provide  
392 such clear visual feedback as that provided by a mirror and would therefore not permit subjects  
393 to observe and learn their own physical features for recognition in non-contingent self-images.

394

395 We find it unlikely that the fixed sequence had an effect on subject interest for reasons  
396 previously mentioned, such as the fact that stimulus presentation was of short duration (30 s) and  
397 that trials were generally spaced out over time. Furthermore, had the fixed sequence had an  
398 effect we might expect a steady decrease in interest as trials progressed, due to habituation to  
399 both the experimental procedure and the presentation of stimuli, but this is not what was  
400 observed.

401

402 Overall, the most striking result was the high level of interest in non-contingent footage of self,  
403 similar to interest in unfamiliar (but not familiar) individuals, suggesting that subjects may have  
404 perceived themselves as unknown conspecifics in the non-contingent footage. To address this  
405 hypothesis, we carried out the second part of the experiment, which consisted of providing  
406 subjects with extended experience of self-reflections by providing them with a mirror for three  
407 consecutive months. We predicted that, if bonobos are capable of self-recognition, as has been  
408 previously demonstrated (Hyatt & Hopkins, 1994; Westergaard & Hyatt, 1994; Walraven, Van  
409 Elsacker & Verheyen, 1995), then increased mirror experience might enable subjects to form a  
410 mental representation of their morphological self, which might then pave the way for self-  
411 recognition from non-contingent self-images. Following the mirror exposure phase, subjects  
412 were retested with the two critical stimuli, non-contingent footage of self (*NC self*) and footage  
413 of an unknown individual (*unknown*), between 10-20 days after the mirror was removed. These  
414 trials were thus carried out almost two years after the corresponding trials for the first part of the  
415 experiment, ruling out simple habituation effects. Considering that the video clips were only 30s  
416 long and shown only once to each subject, it seems unlikely that this experience would have had

417 a major effect on performance if shown a second time 22 months later. Our findings showed that  
418 after prolonged mirror exposure, subject interest in the non-contingent footage of self  
419 significantly decreased, while interest levels for the footage of an unknown individual remained  
420 the same. We suggest that prolonged mirror exposure may have allowed the subjects to form a  
421 visual mental representation of self, which then affected their future interest in non-contingent  
422 footage of themselves. The observed drop in interest might be explained as subjects perceiving  
423 their own footage as “familiar” following the mirror exposure, while the footage of unknown  
424 conspecifics remains novel and of high interest.

425

426 We suggest that given sufficient experience bonobos appear to acquire the ability to use the two-  
427 dimensional cues, provided by a mirror-reflection of themselves, to recognise and learn about  
428 their own physical characteristics and features, which then transfers and generalises to self  
429 depictions detached from the here and now. This was evidenced by the fact that, when presented  
430 with a non-contingent video of self after lengthy mirror exposure, interest in the stimulus was  
431 significantly decreased compared to before the mirror experience, suggesting that the self-image  
432 was now perceived as familiar. Crucially, in the control condition (*unknown*), no such decrease  
433 in interest was observed upon stimulus presentation. Whether this is evidence of self-recognition  
434 cannot be concluded here.

435

## 436 **Conclusion**

437 While this experimental paradigm, investigating bonobos’ responses to different images of self,  
438 and known and unknown conspecifics, does not permit us to draw any conclusion regarding self-

439 recognition from either a contingent video self-image or a mirror-image, we have gained some  
440 insight into the bonobos capacity to form a visual mental representation of self and the ability to  
441 later recognise this self-image from non-contingent video footage. If our interpretations are  
442 correct then the implications of these findings may not only provide additional evidence that  
443 bonobos are capable of some form of self-recognition by perceiving themselves as distinct  
444 entities but also that there may be some form of continuity to the perceived self given the fact  
445 that they might be able to recognise themselves from images that are not from the ‘here and  
446 now’. This sense of continuity has been argued to be one of several a criteria of self-concept  
447 (Gallup, 1998).

448

449 Much remains to be elucidated regarding the mechanisms and the implications of the great apes’  
450 capacity for the development of self-recognition. Our data suggest that three months’ of mirror  
451 experience is sufficient to develop and memorise a visual mental representation of self, but how  
452 much mirror-exposure is necessary minimally? How does such self-recognition persist through  
453 time in the absence of one’s mirror image? Calhoun & Thompson (1988) found that young  
454 chimpanzees were still capable of mirror self-recognition even after one year with no mirror-  
455 exposure, suggesting that once developed the capacity remains perhaps indefinitely. A  
456 philosophically and empirically interesting problem also concerns the implications of self-  
457 recognition for questions about self-awareness and awareness of others. As mentioned, mirror  
458 self-recognition has also been demonstrated in other species particularly dolphins, and elephants,  
459 which has led to further claims about their cognitive capacities, such as having “...complex  
460 social understanding and empathic behaviour” (Prior, Schwarz & Güntürkün, 2008, p.1642).  
461 Mirror self-recognition, in other words, may just be one part of a package of cognitive capacities

462 obtained from convergent evolution (Plotnik, De Waal & Reiss, 2006). Whether or not there are  
463 such intrinsic links, such as suggested by Gallup (1982) in terms of connection between self-  
464 recognition and empathy, or even theory of mind (e.g. Gallup, 1991; Gergely, 1994; Suddendorf  
465 & Collier-Baker, 2009; Anderson & Gallup, 2015; Dale & Plotnik, 2017), needs to be addressed  
466 with further research.

467

### 468 **Acknowledgements**

469 We thank “La Vallée des Singes” and its director, Emmanuel Le Grelle, as well as “Le  
470 Conservatoire pour la Conservation des Primates” for allowing access to the study site and  
471 subjects. We also thank keepers, Carole Michelet, Franck Alexieff, Lise Morel, Jérémy Mergault  
472 and Alexandre Albert for their valuable help in carrying out the experiment. Many thanks to  
473 Christof Neumann for valuable discussions and support.

# Figure 1

Portable acrylic panel for stimulus presentation.

(A) Video camera and iPad displaying a non-contingent video stimulus. (B) Video camera and one-way mirror (front). (C) Video camera and one-way mirror (back). Photos by G. Shorland.

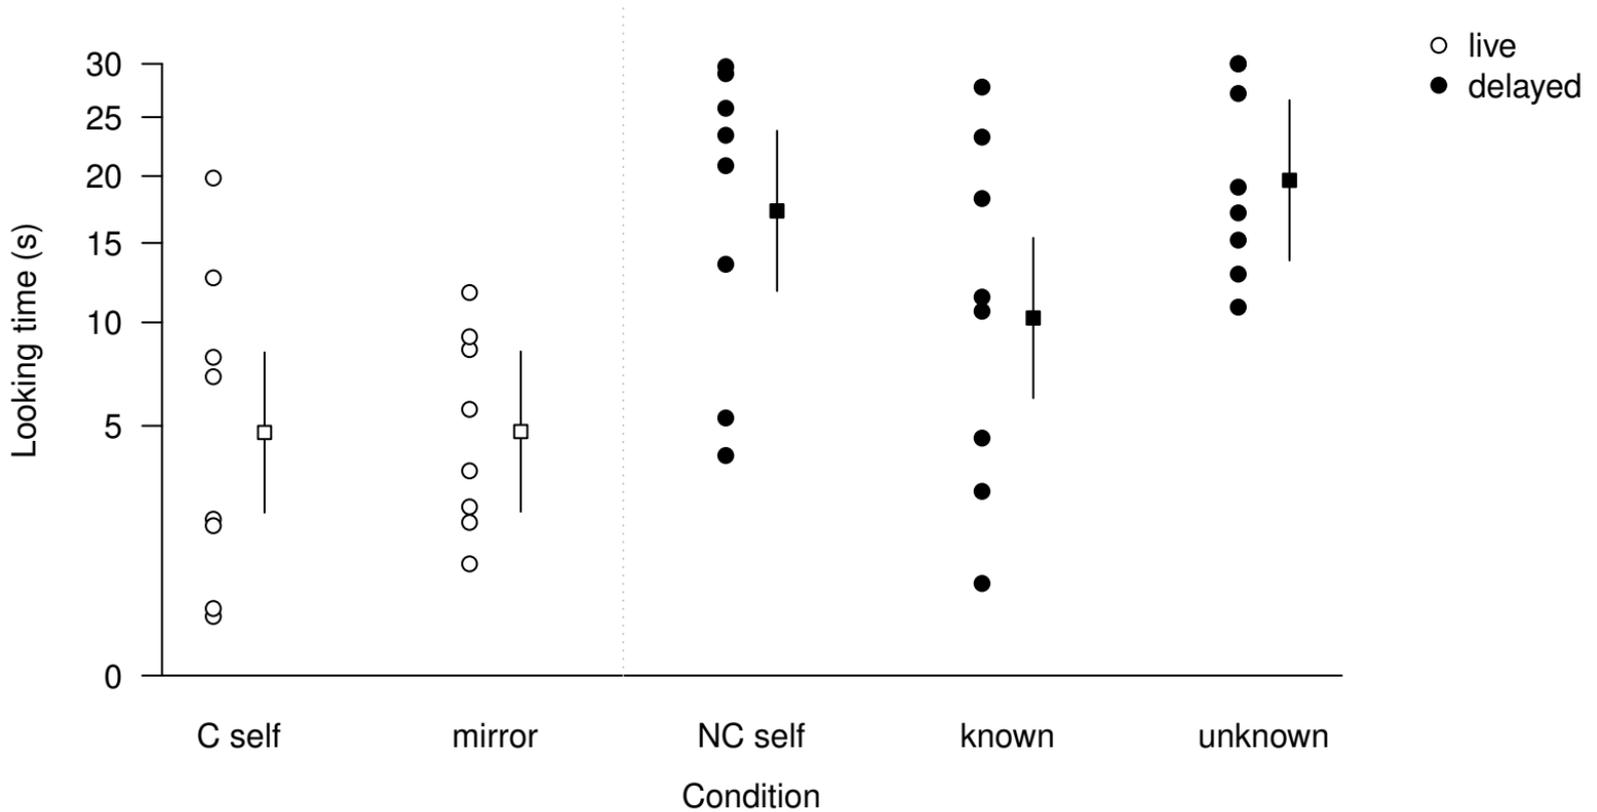

*\*Note: Auto Gamma Correction was used for the image. This only affects the reviewing manuscript. See original source image if needed for review.*

**Figure 2** (on next page)

Subject looking time and model predictions for the five test conditions.

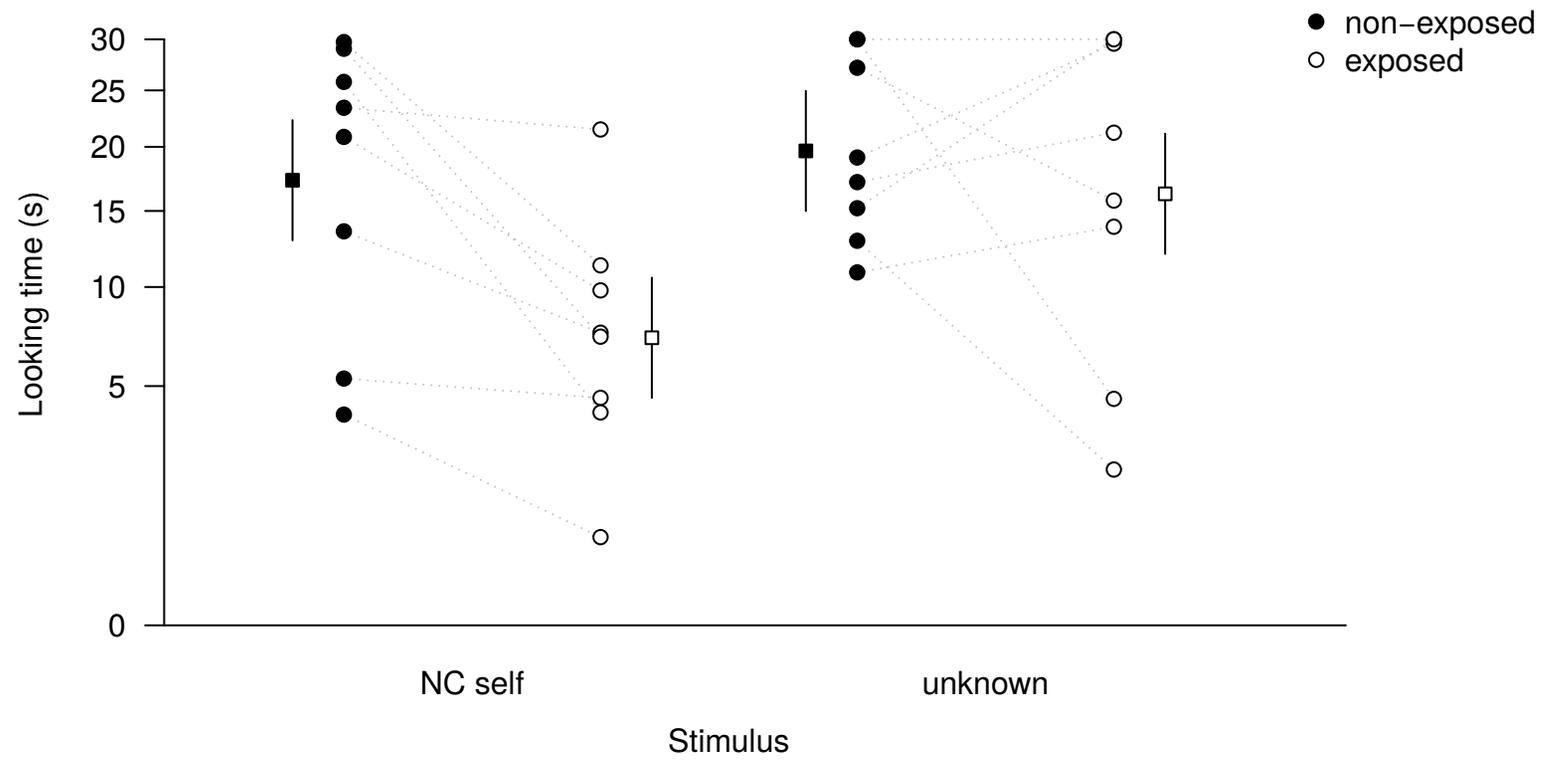

Looking time (circles) and model predictions (squares) with 95% confidence interval; note that looking time was square root transformed for modelling. Conditions are presented chronologically from left to right.

**Figure 3**(on next page)

Subject looking time and model predictions before and after mirror exposure.

Looking time (circles) before and after three-months *ad libitum* mirror exposure. Model predictions (squares) are given with 95% confidence intervals; note that looking time was square root transformed for modeling.

**Table 1** (on next page)

Study subjects housed at La Vallée des Singes primate park, France.

Individuals having participated in all trials are indicated in bold (N=8). Individuals marked by an asterisk initially participated but were excluded for reasons detailed below. Age-class as defined by Kano (1984) at beginning of study.

1 **Table 1.** Study subjects housed at La Vallée des Singes primate park, France

Individual	Code	Sex	Age-Class	Year of birth
Daniela	DNL	F	Adult	1968
<b>Lisala</b>	<b>LSL</b>	<b>F</b>	<b>Adult</b>	<b>1980</b>
Ukela	UK	F	Adult	1985
Bondo *	BO	M	Adult	1991
<b>Kirembo</b>	<b>KI</b>	<b>M</b>	<b>Adult</b>	<b>1992</b>
<b>Ulindi</b>	<b>UL</b>	<b>F</b>	<b>Adult</b>	<b>1993</b>
<b>Diwani</b>	<b>DW</b>	<b>M</b>	<b>Adult</b>	<b>1996</b>
<b>David</b>	<b>DV</b>	<b>M</b>	<b>Adult</b>	<b>2001</b>
<b>Khaya</b>	<b>KH</b>	<b>F</b>	<b>Adult</b>	<b>2001</b>
<b>Lingala</b>	<b>LNG</b>	<b>F</b>	<b>Sub-adult</b>	<b>2003</b>
Lucy *	LY	F	Sub-adult	2003
<b>Kelele</b>	<b>KEL</b>	<b>M</b>	<b>Sub-adult</b>	<b>2004</b>
Luebo *	LUE	M	Sub-adult	2006
Nakala *	NK	F	Juvenile	2007
Loto	LO	M	Juvenile	2009
Moko	MO	M	Infant	2012
Khalessi	KLS	F	Infant	2012

2 Individuals having participated in all trials are indicated in bold (N=8). Individuals  
3 marked by an asterisk initially participated but were excluded for reasons detailed  
4 below. Age-class as defined by Kano (1984) at beginning of study.

**Table 2** (on next page)

Result of the LMM testing the effect of condition on looking time.

1 **Table 1.** Result of the LMM testing the effect of condition on looking time

	Estimate	Standard error	<i>t</i>
Intercept	3.18	0.44	7.18
- <i>Mirror</i>	0.01	0.49	0.02
- <i>NC Self</i>	1.98	0.49	4.03
- <i>Known</i>	1.03	0.49	2.08
- <i>Unknown</i>	2.26	0.49	4.58
- <i>Age</i>	-0.12	0.03	-3.75

2

**Table 3** (on next page)

Result of the LMM, testing the effects of stimulus identity (self vs. unknown) and mirror-exposure (non-exposed vs. exposed) on looking time.

1 **Table 1.** Result of the LMM, testing the effects of stimulus identity (self vs. unknown) and mirror-  
2 exposure (non-exposed vs. exposed) on looking time.

	Estimate	Standard error	<i>t</i>
Intercept	5.85	0.35	16.63
- Mirror-exposure (exposed)	-0.40	0.39	-1.04
- Stimulus identity (Self)	-0.27	0.39	-0.71
Age	-0.17	0.03	-6.41
Exposure : Self	-1.07	0.55	-1.96
