The question of whether animals have some sort of self-awareness is a topic of continued debate. A necessary precondition for self-awareness is the ability to visually discriminate the self from others, which has traditionally been investigated through mirror self-recognition experiments. Although great apes generally pass such experiments, interpretations of results have remained controversial. The aim of this study was to investigate how bonobos (*Pan paniscus*) respond to different types of images of themselves and others, both before and after prolonged mirror exposure. We first presented mirror-naïve subjects with representations of themselves in three different ways (mirror image, contingent and non-contingent video footage) as well as representations of others (video footage of known and unknown conspecifics). We found that subjects paid significantly less attention to contingent images of themselves (mirror, video footage) than to non-contingent images of themselves and unfamiliar individuals, suggesting they perceived the non-contingent self-image as novel. We then provided subjects with three months of access to a large mirror centrally positioned in the enclosure. Following this manipulation, subjects showed significantly reduced interest in the non-contingent self-images, while interest in unknown individuals remained unchanged, suggesting that the mirror experience has led to a fuller understanding of their own self. We discuss implications of these findings for the on-going debate on self-awareness in animals.

9 Abstract

10 The question of whether animals have some sort of self-awareness is a topic of continued debate.
11 A necessary precondition for self-awareness is the ability to visually discriminate the self from
12 others, which has traditionally been investigated through mirror self-recognition experiments.
13 Although great apes generally pass such experiments, interpretations of results have remained
14 controversial. The aim of this study was to investigate how bonobos (*Pan paniscus*) respond to
15 different types of images of themselves and others, both before and after prolonged mirror
16 exposure. We first presented mirror-naive subjects with representations of themselves in three
17 different ways (mirror image, contingent and non-contingent video footage) as well as
18 representations of others (video footage of known and unknown conspecifics). We found that
19 subjects paid significantly less attention to contingent images of themselves (mirror, video
20 footage) than to non-contingent images of themselves and unfamiliar individuals, suggesting
21 they perceived the non-contingent self-image as novel. We then provided subjects with three
22 months of access to a large mirror centrally positioned in the enclosure. Following this
23 manipulation, subjects showed significantly reduced interest in the non-contingent self-images,
24 while interest in unknown individuals remained unchanged, suggesting that the mirror
25 experience has led to a fuller understanding of their own self. We discuss implications of these
26 findings for the on-going debate on self-awareness in animals.

27

28 Introduction

29 A fundamental question in comparative cognition is whether, or to what degree, non-human
30 animals have something akin to self-awareness, that is, whether they can recognise themselves as
31 separate from others and the environment. Related to this is the question of whether animals,
32 other than humans, have some understanding of their own mental states. It is generally accepted
33 that self-awareness presupposes self-recognition of the body, such as its visual appearance,
34 which is empirically easier to address than mentalistic notions of the self. Since the 1970s
35 mirrors have been used as the main tool to investigate self-recognition in the visual domain.
36 Evidence for self-recognition is either in the form of spontaneous, self-directed, exploratory
37 behaviours to the mirror image (Swartz, Sarauw & Evans, 1999) or subjects targeting visual
38 markings administered to a body part that is not visible without the aid of a mirror (the “mirror-
39 mark” test; Gallup, 1970).

40

41 Gallup’s (1970) research on chimpanzees and macaques was pioneering, followed by studies on
42 a range of other primate species, including humans (Amsterdam, 1972), chimpanzees (Lethmate
43 & Dücker, 1973; Suárez & Gallup, 1981; Calhoun & Thompson, 1988; Swartz & Evans, 1991;
44 Lin, Bard & Anderson, 1992; Povinelli et al., 1993), bonobos (Hyatt & Hopkins, 1994;
45 Westergaard & Hyatt, 1994; Walraven, Van Elsacker & Verheyen, 1995), gorillas (Suárez &
46 Gallup, 1981; Ledbetter & Basen, 1982; Posada & Colell, 2007), orang-utans (Lethmate &
47 Dücker, 1973; Suárez & Gallup, 1981), gibbons and siamangs (Lethmate & Dücker, 1973;
48 Inoue-Nakamura, 1997; Suddendorf & Collier-Baker, 2009), monkeys (Lethmate & Dücker,
49 1973; Inoue-Nakamura, 1997) and prosimians (Inoue-Nakamura, 1997) (see Anderson, 1984 for
50 review in primates).

51 Within the non-human primates, great apes generally appear to be capable of mirror self-
52 recognition (see Swartz, Sarauw & Evans, 1999 for review), although there are also multiple
53 reports of failure (e.g., gorillas: Shillito et al., 1999). In bonobos, evidence for mirror self-
54 recognition is in terms of mirror-guided, self-directed behaviours, e.g., subjects picking the teeth
55 or eyes (Hyatt & Hopkins, 1994; Westergaard & Hyatt, 1994), in some instances from first
56 exposure (Walraven, Van Elsacker & Verheyen, 1995). Monkeys (*Macaca silenus*, *Mandrillus*
57 *sphinx*, *Papio hamadryas*, *Ateles sp.*, *Cebus apella*) generally fail the ‘mirror-mark’ test
58 (Lethmate & Dücker, 1973; Ujhelyi et al., 2000; Heschl & Fuchsbichler, 2009; Suddendorf &
59 Collier-Baker, 2009) and we are not aware of any positive evidence for spontaneous, self-
60 directed behaviours in front of mirrors (Inoue-Nakamura, 1997). In one study, Hauser et al.
61 (1995) used a modified ‘mirror-mark’ test by colour-dying cotton-top tamarins’ (*Saguinus*
62 *oedipus*) head hair and reported that individuals touched their heads more often and looked in the
63 mirror longer than controls. However, the study was criticized because results were not based on
64 blind video scoring (Anderson & Gallup, 1997). In a follow-up study, Hauser (2001) then failed
65 to replicate the original findings but argued that subjects had witnesses other group members
66 with colour-dyed hair, suggesting that this may have lowered their interest.

67

68 Mirror experiments have also been conducted with non-primate species with positive evidence in
69 bottlenose dolphins (Marten & Psarakos, 1994; Reiss & Marino, 2001), Asian elephants (Plotnik,
70 de Waal & Reiss, 2006) and even manta rays, the biggest brained of all fish (Ari & D’Agostino,
71 2016). At the same time, small-brained species, such as great tits, (Kraft et al., 2017) or cichlid
72 fish (Hotta, Komiyama & Kohda, 2018), typically fail mirror self-recognition tasks, suggesting
73 that mirror self-recognition may be a property of large brains, regardless of phylogeny (but see

74 Gallup & Anderson, 2018). However, there are claims of mirror-self recognition in Clark's
75 nutcrackers (Clary & Kelly, 2016), Eurasian magpies (Prior, Schwarz & Güntürkün, 2008; but
76 see Anderson & Gallup, 2015) and cleaner wrasse (Kohda et al., 2019) but not in giant pandas
77 (Ma et al., 2015), suggesting that the complexity of a species' social life may also play a role
78 (Gallup, 1998; Prior, Schwarz & Güntürkün, 2008).

79

80 In humans and great apes, the capacity to recognise one's self in a mirror emerges gradually and
81 with experience, usually starting with social behaviours directed at the mirror (e.g., threatening
82 or vocalising; Gallup, 1970), followed by spatial exploration (e.g., reaching or looking behind
83 the mirror), contingency exploration (movements of mirror-image relative to subject's body) and
84 self-exploration (teeth, eyes or genital regions; Swartz, Sarauw & Evans, 1999). In Western
85 human cultures, self-directed behaviours usually appear from 15-18 months of age and become
86 fully expressed by 24 months, while photo self-recognition occurs later (e.g., Courage et al 2004;
87 Amsterdam, 1972; Lewis & Brooks-Gunn, 1979; but see Keller et al., 2004, 2005; Kärtner et al.,
88 2012 for non-western cultures). In chimpanzees, early reactions to mirrors are similar in kind but
89 do not emerge before 24 months (Lin, Bard & Anderson, 1992). Also, there are large individual
90 differences with either much delayed onset (around 60 months: Swartz, Sarauw & Evans, 1999)
91 or no onset at all (e.g., Swartz & Evans, 1991; Povinelli et al., 1993; Walraven, Van Elsacker &
92 Verheyen, 1995).

93

94 Mirror self-recognition studies have caused much debate on how such data should be interpreted.
95 On one end of the spectrum is the interpretation that positive evidence is an indicator of self-
96 awareness (Inoue-Nakamura, 1997; Gallup, 1998; Swartz, Sarauw & Evans, 1999; Plotnik, de

97 Waal & Reiss, 2006) or a self-concept (“...a sense of continuity, a sense of personal agency and
98 a sense of identity”; Gallup 1998, p. 240). At the other end, reactions towards administered
99 marks have been interpreted as mere artefacts of experimental manipulations and that mirror
100 experiments reveal nothing about cognitive capacities (Heyes, 1994, 1995, 1996). More
101 intermediate positions are that such behaviour qualifies as evidence for self-perception, that is,
102 recognising one’s own visual appearance (Nielsen, Suddendorf & Slaughter, 2006) and perhaps
103 even that one’s own body is a separate entity from the surrounding world (a ‘body concept’). The
104 ‘body-concept’ hypothesis has been investigated in developing children, with the conclusion that
105 such awareness emerges in the second year of life, correlated with passing the ‘mirror-mark’ test
106 (Moore et al., 2007). The notion of a ‘body concept’ is also key to an alternative hypothesis to
107 self-recognition: kinaesthetic-visual matching. Here, the idea is that subjects act on the
108 contingency between the kinaesthetic sensations (caused by their body movements) and the
109 corresponding movements of the image in the mirror (Mitchell, 1993, 1997). Mirror self-
110 recognition, however, does not predict perpetual kinaesthetic-visual matching; subjects may
111 simply look at the mirror and know that what they see is them (Mitchell 1993).

112

113 Another way of testing self-recognition is by presenting non-contingent images, usually delayed
114 videos or simply photographs. Infants as young as 5 months appear to discriminate between
115 video images of themselves and those of peers or objects (Legerstee, Anderson & Schaffer,
116 1998) and from 18-24 months they start to show the tell-tale spontaneous behaviours, such as
117 exploration of visually inaccessible body parts, in the absence of contingency cues (Lewis &
118 Brooks-Gunn, 1979). Between 24 and 48 months the emergence of self-recognition from non-
119 contingent images becomes fully established, suggesting that the task is more difficult than self-

120 recognition in a mirror (Povinelli, Landau & Perilloux, 1996). In particular, 24-36 month-old
121 children had more difficulties to infer the presence of a sticker on their heads from watching
122 delayed video image of themselves than 36-48 month-old children. In a more recent study, Hirata
123 et al. (2017) used a similar variant of the ‘mark-test’ to test five subadult chimpanzees with
124 extensive mirror experience (3 of 5 recognised themselves in mirrors). Here, subjects were tested
125 with live video feedback, short-delayed video feedback (i.e., 1-4 seconds) and long-delayed
126 video footage of themselves (one week). Among the control conditions, the authors used video
127 footage of humans but not of conspecifics. The finding was that the three subjects capable of
128 mirror self-recognition removed stickers placed on their heads more effectively and exhibited
129 more self-directed behaviours than the other two individuals, when shown live and short-delayed
130 video feedback but not when shown long-delayed video footage or other control conditions. In
131 sum, self-recognition from delayed, non-contingent self-images may thus be the most stringent
132 test that an individual (human or non-human) possesses a visual mental representation of their
133 own appearance, and this appears to require prior experience with mirrors.

134

135 In this study, we investigated whether bonobos had a generalised understanding of their own
136 physical appearance and whether this was dependent of experience with mirrors. To address this,
137 we tested how subjects responded to different visual images of themselves and others, including
138 when contingency cues were absent, and how mirror exposure influenced their performance. We
139 hypothesised that mirror-naïve individuals did not have a full understanding of their own visual
140 appearance, but that prolonged mirror experience could provide subjects with crucial experience.
141 To address this, we tested mirror-naïve subjects with different visual representations of
142 themselves and others, including non-contingent video footage of themselves. Two years later,

143 following a 3-month period of *ad libitum* access to a mirror, we retested the same subjects again
144 with the two critical conditions, i.e., non-contingent representations of themselves and others.
145 We assessed subjects' interest in the different stimuli by comparing looking times, based on the
146 fact that both human and nonhuman primates spend more time looking at novel than familiar
147 faces and other stimuli (e.g., patterns: (Fantz, 1964; Gunderson & Sackett, 1984; Gunderson &
148 Swartz, 1985); objects: (Bachevalier, Brickson & Hagger, 1993; Pascalis & Bachevalier, 1998);
149 conspecific faces: (Pascalis & Bachevalier, 1998; Gothard, Erickson & Amaral, 2004; Gothard,
150 Brooks & Peterson, 2009; but see Winters, Dubuc & Higham, 2015 for criticism). We predicted
151 that stimuli perceived as unfamiliar should cause longer looking times than stimuli perceived as
152 familiar (Pascalis & de Schonen, 1994).

153 **Methods**

154 **Study site & subjects**

155 The study was carried out at La Vallée des Singes Primate Park in Romagne (France) with a
156 group of bonobos (2014: N=17; 2016: N=20; table 1) housed in an indoor enclosure (400m²)
157 with access to two outdoor wooded islands (11,500m²). Experiments were carried out from
158 January to July 2014 and from February to July 2016. Eight subjects (table 1) participated in all
159 trials, which involved a 'looking-time' bias task with sequential stimulus presentation, a
160 paradigm originally developed in the late 1950s for research with pre-verbal human infants (e.g.,
161 Fantz, 1963; Winters, Dubuc & Higham, 2015).

162

163 Prior to testing, individuals were exposed to the equipment during one week to minimise any
164 potential effects of novelty. Videos stimuli were then presented by means of an APPLE iPad

165 (screen size approx. 15 x 20 cm) placed behind a transparent Acrylic panel (Fig. 1a) to which a
166 PANASONIC HC-V100 full HD camera was mounted to record the subjects' reactions face-on.
167 The mirror stimulus was presented by means of a one-way mirror (25 x 30 cm), attached behind
168 the same panel (Fig. 1b and c).

169

170 **Part 1 - Before mirror exposure**

171 The first part of the experiment was carried out in 2014 with N=8 subjects (4 males, 4 females,
172 age range 9–34 years), none of whom had any known experience with mirrors. The experiment
173 comprised five experimental conditions presented to all subjects in the following order: (1)
174 contingent video footage of self (live feedback of self, visible on an iPad: *C self*); (2) contingent
175 mirror image of self (live depiction of self, visible in a one-way mirror: *mirror*); (3) non-
176 contingent video footage of self (previously recorded video footage of self, visible on an iPad:
177 *NC self*); (4) non-contingent video footage of known group member (previously recorded video
178 footage of other group member visible on an iPad: *known*); (5) non-contingent video footage of
179 unknown conspecific (previously recorded video footage of unfamiliar conspecific visible on an
180 iPad: *unknown*) (see ESM 1 and 2).

181

182 Footage for '*NC self*' and '*known*' were recorded during the '*mirror*' and '*C self*' conditions.
183 Footage for '*unknown*' (N=2 males; N=1 female) were recorded at the 'Lola ya Bonobo'
184 Sanctuary in the Democratic Republic of the Congo (see ESM 3 and 4 for sample footage). In
185 both the '*known*' and '*unknown*' conditions, the footage showed generally inactive individuals
186 also glancing at the camera from time to time. Footage for stimulus presentation was selected at
187 random, resulting in N=6 same-sex pairs and N=2 opposite-sex pairs for the '*known*' condition

188 and N=4 same-sex and N=4 opposite-sex pairs for the '*unknown*' condition. An alternative
189 design would have been to control for sex (i.e., to compare same-sex and different-sex footage)
190 or to simply use same-sex footage. As this would have created sample size issues we opted for
191 randomly assigning footage of '*known*' and '*unknown*' individuals to our eight subjects.

192

193 Each subject was presented with each of the five conditions once and in the same sequential
194 order over an eight-month period (see Table S2). Stimuli were presented only very briefly, for a
195 total of 30s, starting with the first glance from the subject towards the stimulus. A trial was
196 terminated after 30s or as soon as a subject left. We are aware of the fact that fixed order
197 stimulus presentation designs carry the disadvantage of potentially creating cross-condition
198 dependencies. A completely randomised design might have been preferable but not practical due
199 to the low number of subjects available for testing. In particular, we regarded it as essential that
200 all subjects entered part 2 of the experiment with the exact same stimulus history. We also
201 considered it unlikely that dependencies across conditions played a role because stimulus
202 exposure was very short (30s) and intervals between subsequent presentations were long (median
203 = 38.5 days, range: 0-95 days).

204

205 Trials were carried out only when a subject was alone and inactive (i.e., resting or observing) in
206 one of the indoor cages and at a suitable orientation and distance from the corridor (0.3-2.0 m).
207 The subject was exposed to one of two portable devices, an iPad or a one-way mirror, each with
208 a camera mounted to record looking responses (Fig. 1).

209

210 We measured looking-time during stimulus presentation. Looking time as a proxy for familiarity
211 is not uncontroversial (e.g. Winters, Dubuc & Higham 2015) but appears to be a reliable variable
212 in face recognition tasks in which primates generally look longer to unfamiliar than familiar
213 (conspecific) faces (Pascalis & de Schonen, 1994; Pascalis & Bachevalier, 1998; Gothard,
214 Erickson & Amaral, 2004; Gothard, Brooks & Peterson, 2009; Fujita, 1987; Demaria & Thierry,
215 1988). Looking-time was coded post-hoc from the video recordings. Coding was blind insofar as
216 all videos were randomly labelled so that the rater (GS) was unable to infer the experimental
217 condition. Videos were analysed frame-by-frame with MPEG Streamclip 1.9.2. Looking time
218 was determined by measuring the duration between the first glance towards the stimulus and the
219 beginning of gaze aversion. If multiple gazes occurred over the 30s stimulus presentation, we
220 added them up. All clips were coded independently and blindly by a second rater (EG), which
221 did not reveal any reliability issues (Pearson's correlation coefficient, $r = 0.93$, $N=56$).

222

223 Eight of 17 adult group members were tested and analysed in this study (see Table 1). Regarding
224 the remaining individuals ($N=9$): One adult male (BO) participated in all experimental conditions
225 but had to be excluded due to poor video quality that prevented accurate coding. Two further
226 individuals (NK and LUE) also had to be excluded because they were too close to the camera,
227 which prevented reliable coding of looking time. One adult female (LY) had to be excluded
228 because she only participated in two conditions. Finally, we were unable to test the remaining
229 two adult females (DNL and UK) due to their lack of interest and participation. The dependent
230 infants and juveniles (LO, MO and KLS) were not tested.

231

232 Part 2 - After mirror exposure

233 Fifteen months after the first part of the experiment, subjects were provided with prolonged
234 access to a large mirror (45 x 115 cm) to gain extended experience with mirror reflections of
235 themselves. The mirror was placed in front of a resting platform in the indoor enclosure allowing
236 extensive *ad libitum* access to all individuals over a period of three months (i.e., from Nov 2015
237 to Feb 2016; approx. 2,000 hours). At this time of year, the group was kept inside due to cold
238 weather conditions and the park was closed to the public. Although we did not quantify the
239 amount of time and manner by which subjects interacted with the mirror, all subjects had
240 countless opportunities to familiarise themselves with their own mirror reflections. Anecdotal
241 reports from the keepers suggested that subjects did not spend noticeable amounts of time in
242 front of the mirror to inspect themselves but, in hindsight, it would have been interesting to
243 collect systematic data on how subjects behaved in front of the mirror, both quantitatively and
244 qualitatively.

245

246 We were mainly interested in the effect of mirror experience on subjects' perception of their own
247 and others' non-contingent images. To this end, we retested all individuals that had participated
248 in part 1 (N=8) with the two critical conditions from part 1, i.e., non-contingent video footage of
249 themselves and of unknown conspecifics. Stimulus presentation began 10 - 20 days after removal
250 of the mirror. All aspects of presentation were identical to part 1, including the video footage.

251 The time lapse between the first and second stimulus presentation for a given subject and
252 condition was held constant for each subject and averaged at approximately 22 months (see
253 Table S2).

254

255 Statistical analyses

256 In a first analysis, prior to the 3-month mirror exposure, we modelled looking time as the
257 response variable, experimental condition as the main predictor variable and subject ID as the
258 random intercept in a linear mixed model (LMM). We added age as a control predictor to
259 account for the possibility that younger individuals might show more interest than older
260 individuals (Westergaard & Hyatt, 1994; Walraven, Van Elsacker & Verheyen, 1995). Looking
261 time and age were square root transformed to achieve homogenous and approximately normally
262 distributed residuals. We tested this full model against an informed null model (Forstmeier &
263 Schielzeth, 2011), which only included age as predictor and subject ID as random intercept. We
264 tested the difference between the full and null model with a likelihood ratio test (LRT, Dobson,
265 2002). Note that this comparison is equivalent to testing of ‘experimental condition’ (models
266 with vs. without experimental condition as variable). Post hoc diagnostics were implemented in
267 order to test the stability of the model. This entailed running the full model eight times, each time
268 removing data of one of the eight individuals and permitted us to verify whether one of the
269 individuals was influential with respect to the interpretation of our model results. Results of this
270 procedure indicated stable model results, that is, exclusion of any one individual did not change
271 the conclusions of our analysis.

272

273 In a second analysis, we tested how looking time was affected by the interaction between
274 stimulus type (self vs. unknown, i.e., self Y/N) and mirror exposure (non-exposed vs. exposed,
275 i.e., exposed Y/N), again with a Linear Mixed Model. Once again, we controlled for age, which
276 was included in the respective null model, and implemented post-hoc diagnostics to test the
277 stability of the model, which returned stable model results.

278

279 Statistical analyses were carried out with R v. 3.1.2 and lme4 v. 1.1-11 (R Core Team, 2014;

280 Bates et al., 2015). Data are available in the electronic supplementary material (ESM 5).

281 **Compliance with ethical standards**

282 All applicable international, national and institutional guidelines for the care and use of animals

283 were followed. The study was authorised and given ethical approval by the “La Vallée des

284 Singes” scientific coordinator and zoological director. Trials were carried out opportunistically

285 when and where subjects felt so inclined. The study was in line with the ARRIVE guidelines and

286 recommendations from the EAZA and the AFdPZ code of ethics.

287 **Results**

288 The first part of the experiment consisted of exposing subjects to different motion images of

289 themselves, of other group members and of unfamiliar conspecifics (see Table S2). The results of

290 the model indicated that looking time was affected by experimental condition (LRT, $\chi^2 = 25.87$,

291 d.f. = 4, $P < 0.001$; Fig. 2; Table 2), with short looking times in the ‘*C self*’ and ‘*mirror*’

292 conditions (<5.0 of 30s) and three-fold longer looking times in the ‘*NC self*’ and ‘*unknown*’

293 conditions, whereas looking times to ‘*known*’ individuals were intermediate (Fig. 2: model

294 estimates, Table 3: descriptive data). In sum, subjects showed most interest in images of

295 strangers and non-contingent images of themselves and least interest in contingent images of

296 themselves (video clips and mirror reflections), suggesting that non-contingent self-images were

297 perceived in the same way as unknown individuals.

298

299 We then provided subjects with three months of *ad libitum* mirror access. Following this
300 manipulation and almost two years after the previous trials, subjects were retested with non-
301 contingent footage of themselves (*NC self*) and strangers (*unknown*), the two conditions that
302 elicited most interest before (Fig. 2).

303

304 When comparing interest across the two time periods, the full model was significantly different
305 from the null model (LRT, $\chi^2=18.06$, d.f.=3, $P<0.001$; Fig. 3, Table 4), indicating that looking
306 time differed as a function of mirror-exposure, stimulus identity, and their interaction. The
307 interaction effect was close to significance (LRT, $\chi^2=3.61$, df=1, $P=0.057$), indicating that
308 interest, as measured by looking time, was substantially lower in the '*NC self*' condition after the
309 three-month mirror-exposure than before, which was not the case for the '*unknown*' condition
310 (see fig 3 for model prediction means and SDs). These results suggest that prolonged mirror
311 exposure decreased subject interest in their non-contingent self-images, while interest in stranger
312 individuals remained similar.

313 **Discussion**

314 In this study, we were interested in how prolonged mirror-exposure influenced the response to
315 visual representations of the self. The underlying rationale was that, during human development,
316 recognition of non-contingent footage of the self is cognitively most challenging, suggesting that
317 bonobos may struggle more with such stimuli, compared to contingent depictions of themselves.
318 To address this, we carried out a two-part experiment during which subjects watched motion
319 images depicting either themselves or another individual.

320

321 In the first part, subject responses to three types of self-images (mirror reflection, contingent
322 video footage and non-contingent video footage) were compared with responses to video footage
323 of familiar and unfamiliar conspecifics. Results revealed low interest in the mirror and in
324 contingent self-footage, but high interest in the non-contingent self-footage condition, similar to
325 interest in unfamiliar individuals.

326

327 A first parsimonious explanation of this result might be that bonobos did not recognise
328 themselves in any of the three conditions (mirror, contingent, non-contingent), but that non-
329 contingent movement was simply more interesting than contingent movement. However, this
330 interpretation is at odds with the fact that the '*known*' condition caused less interest than '*non-*
331 *contingent self*' and '*unknown*' conditions, all of which moved in asynchronous ways, so we
332 consider this explanation as unlikely.

333

334 A second explanation for the high interest in the '*non-contingent self*' condition might be that
335 subjects did not recognise themselves and responded as if it were an unfamiliar individuals (fig
336 2) whereas they did recognise themselves in the contingent footage and mirror images. But if
337 they recognised themselves, why did they not engage in the usual tell-tale behaviours of self-
338 recognition, such as exploration of visually inaccessible body parts and contingency testing?
339 One explanation for this curious absence is that stimulus exposure was too short (30s),
340 effectively preventing subjects from engaging in self-exploration. However, it must be stated that
341 during the subsequent prolonged mirror exposure, neither the keepers nor the researchers ever
342 noted self-exploration by subjects. The fact that subjects showed little interest in the contingent
343 stimuli suggests that they were already familiar with their own reflections (from windows, water

344 surfaces or their own shadows), but that this was not be enough to develop a full sense of how
345 one looks.

346

347 In the second part of the experiment, we provided subjects with extended experience of self-
348 reflections by giving them uninterrupted access to a mirror for three consecutive months. We
349 predicted that this experience should enable subjects to familiarise themselves with a wider range
350 of visual depictions of themselves, which would allow them to generalise and form a mental
351 representation of their own visual appearance. When retesting subjects with the two critical
352 stimuli (non-contingent footage of self and unknown individuals), 10-20 days after the mirror
353 was removed, we found that interest in the non-contingent footage significantly decreased, while
354 interest in strangers remained similar (fig. 3), in line with our predictions. In hindsight, an
355 interesting point of comparison would have been to also rerun the '*known*' condition, as a further
356 control. Based on the fact that the subjects had extensive opportunities to observe each other
357 daily, we would not have predicted any change in interest in this condition after the mirror-
358 exposure.

359

360 Could results be explained by low-level stimulus habituation to differences in background? We
361 find this an unlikely scenario since stimulus presentations were exceedingly short (30s) and
362 presented only twice over a period of 22 months, rendering perceptual habituation an implausible
363 scenario. Moreover, responses to non-contingent self and known individuals were different,
364 despite similar backgrounds, while responses to non-contingent self and strangers were similar,
365 despite different backgrounds. Also, it may have been difficult for subjects to pay attention to the

366 backgrounds given the short presentation periods. Explanations based on background, in other
367 words, requires complex and non-parsimonious argumentations that we find unconvincing.

368

369 At the very least, therefore, subjects must have managed to familiarise themselves with all
370 aspects of their visual appearance, allowing them to categorise the ‘*non-contingent self*’ footage
371 as more familiar compared to the stranger footage. But whether or not subjects really proceeded
372 to form a true mental concept of their own visual appearance (“that’s me”), as opposed to some
373 lower level sense of familiarity, will have to be addressed by future research.

374 **Conclusion**

375 Our data suggest that, given sufficient mirror exposure, bonobos acquire the ability to use mirror-
376 reflections of themselves to learn about their own physical appearance. In contrast to other
377 research our results suggest that this level of awareness is detached from the here and now and
378 can include visual non-contingent representations of the self. Whether or not these findings
379 qualify as evidence of self-recognition cannot be decided with our data, due the alternative
380 interpretations outlined before. Much remains to be elucidated regarding the mechanisms and the
381 implications of great apes’ capacity of self-recognition, such as the amount of mirror exposure
382 minimally necessary or the stability of the resulting self-recognition over time (see Calhoun &
383 Thompson (1988) de Veer et al. (2003).

384

385 A philosophically and theoretically interesting problem concerns the implications of self-
386 recognition data for questions about self-awareness and awareness of others. As mentioned,
387 mirror self-recognition has also been demonstrated in non-primate species, particularly dolphins

388 and elephants, which has led to interesting claims, such as them having “...complex social
389 understanding and empathic behaviour” (Prior, Schwarz & Güntürkün, 2008, p.1642) and
390 suggestions that complex cognition emerges through convergent evolution (Plotnik, de Waal &
391 Reiss, 2006; Mitchell, 2012). In this view, self-recognition is to be found in any organism
392 capable of complex cognition, together with empathy, social awareness and theory of mind (e.g.,
393 Gallup, 1991; Gergely, 1994; Suddendorf & Collier-Baker, 2009; Anderson & Gallup, 2015;
394 Dale & Plotnik, 2017) rather than a specifically evolved cognitive specialisation.

395

396 **Acknowledgements**

397 We thank “La Vallée des Singes” and its director, Emmanuel Le Grelle, as well as “Le
398 Conservatoire pour la Conservation des Primates” for allowing access to the study site and
399 subjects. We also thank keepers, Carole Michelet, Franck Alexieff, Lise Morel, Jérémy Mergault
400 and Alexandre Albert for their valuable help in carrying out the experiment. Many thanks to
401 Christof Neumann for his statistical advice and for valuable discussions and support.

Moko	MO	M	Infant	2012
Khalessi	KLS	F	Infant	2012

2 Individuals having participated in all trials are indicated in bold (N=8). Individuals
3 marked by an asterisk initially participated but were excluded for reasons detailed
4 below. Age-class as defined by Kano (1984) at beginning of study.

Table 2 (on next page)

Result of the LMM testing the effect of condition on looking time.

1 **Table 2.** Result of the LMM testing the effect of condition on looking time

	Estimate	Standard error	<i>t</i>
Intercept	3.18	0.44	7.18
Condition (<i>C self</i>)			
- <i>Mirror</i>	0.01	0.49	0.02
- <i>NC Self</i>	1.98	0.49	4.03
- <i>Known</i>	1.03	0.49	2.08
- <i>Unknown</i>	2.26	0.49	4.58
Age	-0.12	0.03	-3.75

2

Table 3 (on next page)

Descriptive results: experimental condition, mirror exposure, median looking-time and quartiles calculated from raw data.

1 **Table 3.** Descriptive results: experimental condition, mirror exposure, median looking-time and quartiles
2 calculated from raw data.

Condition	Mirror exposure	Median looking time	Quartiles
<i>C self</i>	non-exposed	4.6	1.4 - 9.3
<i>mirror</i>	non-exposed	4.5	2.2 - 8.7
<i>NC self</i>	non-exposed	22.1	11.5 - 26.6
<i>known</i>	non-exposed	11.1	4.1 - 19.5
<i>unknown</i>	non-exposed	18.1	14.6 - 27.9
<i>NC self</i>	exposed	7.4	4.4 - 10.2
<i>Unknown</i>	exposed	18.5	11.5 - 29.7

3

Table 4(on next page)

Result of the LMM, testing the effects of stimulus identity (self vs. unknown) and mirror-exposure (non-exposed vs. exposed) on looking time.

1 **Table 4.** Result of the LMM, testing the effects of stimulus identity (self vs. unknown) and mirror-
2 exposure (non-exposed vs. exposed) on looking time.

	Estimate	Standard error	<i>t</i>
Intercept	5.85	0.35	16.63
Mirror-exposure (non-exposed)			
- exposed	-0.40	0.39	-1.04
Stimulus identity (non-self)			
- self	-0.27	0.39	-0.71
Mirror exposure : Stimulus identity	-1.07	0.55	-1.96
Age	-0.17	0.03	-6.41
