The extant genera of fur seals and sea lions of the family Otariidae (Carnivora: Pinnipedia) are thought to have emerged in the Pliocene or the early Pleistocene in the North Pacific. Among them, the Steller sea lion (*Eumetopias jubatus*) is the largest and distributed both in the western and eastern North Pacific. In contrast to the limited distribution of the current population around the Japanese Islands that is now only along the coast of Hokkaido, their fossil records have been known from the middle and late Pleistocene of Honshu Island. One such important fossils specimens has been recorded from the upper lower Pleistocene Omma Formation (ca. 1.36-0.83 Ma) in Kanazawa, Ishikawa Prefecture, Japan, which now bears the institutional number GKZ-N 00001. Because GKZ-N 00001 is the earliest fossil having been identified as a species of the sea lion genus *Eumetopias*, it is of importance to elucidate the evolutionary history of that genus. The morphometric comparisons were made among 51 mandibles of fur seals and sea lions with GKZ-N 00001. As results of bivariate analyses and PCA based on 39 measurements for external morphologies with internal structures by CT scan data, there is almost no difference between GKZ-N 00001 and extant male individuals of *E. jubatus*. In this regard, GKZ-N 00001 is identified specifically as the Steller sea lion *E. jubatus*. Consequently, it is recognized as the oldest Steller sea lion in the North Pacific. About 0.8 Ma, the distribution of the Steller sea lion had been already established at least in the Japan Sea side of the western North Pacific.

### 33 **Abstract**

34 The extant genera of fur seals and sea lions of the family Otariidae (Carnivora: Pinnipedia) are  
35 thought to have emerged in the Pliocene or the early Pleistocene in the North Pacific. Among  
36 them, the Steller sea lion (*Eumetopias jubatus*) is the largest and distributed both in the western  
37 and eastern North Pacific. In contrast to the limited distribution of the current population around  
38 the Japanese Islands that is now only along the coast of Hokkaido, their fossil records have been  
39 known from the middle and late Pleistocene of Honshu Island. One such important fossils  
40 specimens has been recorded from the upper lower Pleistocene Omma Formation (ca. 1.36-0.83  
41 Ma) in Kanazawa, Ishikawa Prefecture, Japan, which now bears the institutional number GKZ-N  
42 00001. Because GKZ-N 00001 is the earliest fossil having been identified as a species of the sea  
43 lion genus *Eumetopias*, it is of importance to elucidate the evolutionary history of that genus.  
44 The morphometric comparisons were made among 51 mandibles of fur seals and sea lions with  
45 GKZ-N 00001. As results of bivariate analyses and PCA based on 39 measurements for external  
46 morphologies with internal structures by CT scan data, there is almost no difference between  
47 GKZ-N 00001 and extant male individuals of *E. jubatus*. In this regard, GKZ-N 00001 is  
48 identified specifically as the Steller sea lion *E. jubatus*. Consequently, it is recognized as the  
49 oldest Steller sea lion in the North Pacific. About 0.8 Ma, the distribution of the Steller sea lion  
50 had been already established at least in the Japan Sea side of the western North Pacific.

51

### 52 **Introduction**

53 The extant pinnipeds of the order Carnivora are divided into three families, the Otariidae, the  
54 Odobenidae, and the Phocidae (e.g., *Berta et al., 2018*). Among them, the otariids are distributed

55 mostly in the Pacific Ocean and composed of fur seals and sea lions. Sea lions are generally large  
56 in body size; in particular, the Steller sea lion (*Eumetopias jubatus*) in the North Pacific is the  
57 largest among them. In contrast to the relatively limited distribution of the current population of  
58 the Steller sea lion in Japan, which is now only around Hokkaido (Loughlin *et al.*, 1984; 1987),  
59 their distribution during the Pleistocene is thought to be relatively broad, because their  
60 mandibular and tooth fossils have been known from the Pleistocene of Honshu Island. One such  
61 important fossil specimens has been recorded from the upper lower Pleistocene Omma  
62 Formation (ca. 1.36 – 0.83 Ma) in Kanazawa, Ishikawa Prefecture, Japan, which bears the  
63 institutional number GKZ-N 00001 (Figs. 1, 2; Kaseno, 1951; Shikama, 1953; Mitchell, 1968).  
64 In October 1946, a right mandibular fossil (i.e., GKZ-N 00001) was collected by the late Dr.  
65 Yoshio Kaseno (then Kanazawa University) and third year students of the Biological  
66 Department, Kanazawa Higher Normal School, Ishikawa Prefecture, Japan. The specimen came  
67 from the upper part of the Omma Formation at a road cutting south of Gosyo village (now Gosyo  
68 Town), northeastern end of Kanazawa City, Ishikawa Prefecture, central Japan. While Kaseno  
69 (1951) identified GKZ-N 00001 tentatively as a species of “*Allodesmus*” which is an extinct  
70 pinniped known from the Miocene of the North Pacific, Shikama (1953) pointed out that GKZ-N  
71 00001 might belong to *E. jubatus* (*E. jubata* at that time). Later, Mitchell (1968) also suggested  
72 that GKZ-N 00001 be studied further before being unequivocally identified as conspecific with  
73 *E. jubatus*. Currently, the specific identification of GKZ-N 00001 is still ambiguous and in  
74 controversy (e.g., Kohno & Tomida, 1993; Barnes *et al.*, 2006) and has not been confirmed yet.  
75 At the time when GKZ-N 00001 was found, the Omma Formation had been considered to be  
76 Pliocene in age, but it turned out to be early Pleistocene (ca. 1.36–0.83 Ma) based on the  
77 calcareous microfossil stratigraphy (Takayama *et al.*, 1988). The extant genera in the Otariidae  
78 including *Eumetopias* are considered to be branched off at the end of the Pliocene (Repenning &  
79 Tedford, 1977), and the oldest fossil record of extant otariid genera is known from the late  
80 Pliocene to the early Pleistocene (Berta & Deméré, 1986; Kohno & Yanagisawa, 1997). These  
81 studies suggest that the early Pleistocene that may also correspond to the emergence of the genus  
82 *Eumetopias* is important time to elucidate the evolutionary history of the otariids. Therefore,  
83 highlighting the meaningfulness of proper identification of GKZ-N 00001 is meaningful.

84

## 85 **Materials & Methods**

86 In order to compare fossil specimens with modern taxa, the morphometric analyses are  
87 performed using 51 mandibles of fur seals and sea lions: 12 male and 12 female individuals of  
88 the Steller sea lion *E. jubatus*, three male and 10 female individuals of the Northern fur seal  
89 *Callorhinus ursinus*, 10 male and one female individuals of the Japanese sea lion *Zalophus*  
90 *japonicus*, two male individuals of the Odysseus sea lion *Proterozetes ulysses*, and GKZ-N  
91 00001 (Table 1, Data S1). A total of 21 landmarks are defined with reference to the previous  
92 morphometric research (Berta & Deméré, 1986; Isono, 1998; Adam & Berta, 2002; Brunner,  
93 2004; Boessenecker, 2011; Kienle & Berta, 2015), and a total of 39 measurements are taken  
94 using a digital caliper to the nearest 0.01 mm (Fig. 3, Tables 2, 3, S1).

95 Based on these measurements, bivariate analyses and principal component analysis (PCA) are  
96 performed. PCA is implemented in R 3.5.1 (*R Core Team, 2018*). In addition, the mandibles are  
97 observed with the micro-computed tomographic scanner using Microfocus CT, TXS320-ACTIS  
98 at the National Museum of Nature and Science, Tokyo, Japan.

99

## 100 **Systematic Paleontology**

101 MAMMALIA *Linnaeus, 1758*

102 CARNIVORA *Bowditch, 1821*

103 PINNIPEDIA *Illiger, 1811*

104 OTARIIDAE *Gill, 1866*

105 **Included Genera:** [extant genera] *Arctocephalus Cuvier, 1826; Arctophoca Peters, 1866;*  
106 *Callorhinus Gray, 1859; Eumetopias Gill, 1866; Neophoca Gray, 1866; Otaria Peron, 1816;*  
107 *Phocarctos Peters, 1866; Zalophus Gill, 1866.* [extinct genera] *Eotaria Boessenecker &*  
108 *Churchill, 2015; Pithanotaria Kellogg, 1925; Thalassoleon Repenning & Tedford, 1977;*  
109 *Hydrarctos (de Muizon, 1978) Berta & Deméré, 1986; Proterozetes Barnes et al., 2006* (after  
110 *Berta & Churchill, 2011; Velez-Juarbe, 2017*).

111 **Emended Diagnosis of Family:** [Crown Otariidae (*C. ursinus*, northern sea lion clade, and  
112 southern otariid clade)] single rooted P3, P4, p2, and p4. Pronator teres insertion positioned on  
113 the proximal 40% of the radius. Secondary shelf of the sustentaculum of the calcaneum  
114 developed as a wider shelf (modified from *Churchill et al., 2014*).

115

116 *EUMETOPIAS Gill, 1866*

117 **Included Species:** Only the extant species *Eumetopias jubatus (Schreber, 1776)*.

118 **Remarks:** *Horikawa (1981)* described a partial skeleton including some isolated cheek teeth as  
119 the holotype of a new species in the genus, i.e., *Eumetopias ojiyaensis*, based on comparisons  
120 mainly of the upper incisor and canine with a female of *E. jubatus*. However, the characters he  
121 mentioned (e.g., overall similarity of teeth, condition of accessory cusps on the molar etc.) are  
122 plesiomorphic or nondiagnostic for the sea lions and unavoidable the potential identification of  
123 the holotype to a species of other sea lion genera within the Otariidae because of its  
124 incompleteness. We consider *E. ojiyaensis* a *nomen dubium* and suggest a temporary pending on  
125 both generic and specific identification for its holotype until much better specimens at least  
126 including the mandible will be obtained from the type locality or the same formation.

127 **Diagnosis of Genus:** As for the species.

128

129 *Eumetopias jubatus (Schreber, 1776)*

130 **Emended Diagnosis:** *Eumetopias jubatus* is the largest species in body size (about 3.3 m in  
131 males) among the family Otariidae. The upper and lower canines are large in males, particularly  
132 at the apical ends of roots that are almost evergrowing (less so in females). The mandible is long  
133 and the angle between the horizontal and ascending rami is large (about 130-140 degree) in  
134 contrast to the smaller angle of less than 130 degree in other genera and species. The masseteric

135 fossa is deep and long, especially in older individuals. Postcanines are unicuspid with well-  
136 developed labial and lingual cusps at the base (modified from *Brunner, 2004*).

137 **Dental formula:** 3/2, 1/1, 4/4, 1/1.

138 **Referred specimen:** GKZ-N 00001, incomplete right dentary with right lower canine, left p2,  
139 left and right p4, left P4 and right M1; collected by the late Yoshio Kaseno (then Kanazawa  
140 University) and third year students of the Biological Department, Kanazawa Higher Normal  
141 School, in October 1946. Now this specimen is stored at the Graduate School of Natural Science  
142 and Technology, Kanazawa University (GKZ).

143 **Locality of referred specimen:** GKZ-N 00001 was found at a road cutting south of Gosyo  
144 Town, north-eastern end of Kanazawa City, Ishikawa Prefecture, Japan. The geographical  
145 coordinate is 36° 34 '51 " North Latitude, 136° 40 ' 59" East Longitude. Currently, no  
146 outcrop remains there.

147 **Formation and Age:** GKZ-N 00001 was yielded from the upper part of the Omma Formation. It  
148 is consisted of homogeneous silty fine-grained sandstone in bluish color, from which many  
149 fragmentary remains of molluscs such as *Acila*, *Pecten*, *Venericardia*, *Myodora*, *Cardium*, and  
150 *Diplodonta* have been collected (*Kaseno, 1951*). The geologic age of the Omma Formation  
151 corresponds to the late early Pleistocene (ca. 1.36–0.83 Ma) based on the calcareous microfossil  
152 stratigraphy (*Takayama et al., 1988*). The depositional environment of the Omma Formation is  
153 thought to be cold temperate water within 0–30 m in depth, on a shoreface or inner shelf, the  
154 upper part of the upper shallow-sea zone, on the basis of the habitat preferences of molluscan  
155 fossils collected from a bed slightly higher than the horizon of GKZ-N 00001 (*Tsuzuku,*  
156 *2018MS*).

157 **Associated Mammalian Fossils:** *Matsuura (1996)* reported some metacarpals and phalanges of  
158 possibly otariid pinnipeds. In addition, many cetacean and some sirenian fossils have also been  
159 found from the same formation (*Matsuura & Nagasawa, 2000*), although these have not yet been  
160 described in detail.

161

## 162 **Description**

163 **Mandible (Fig. 1):** GKZ-N 00001 is a right mandible consisting of almost complete horizontal  
164 ramus and broken coronoid process. The c1 and p2 are in place on the horizontal ramus. Both  
165 left and right p4 are also preserved as isolated teeth. In addition, isolated left P4 and right M1 are  
166 also preserved, suggesting that the skull as well as the left mandible might also be preserved at  
167 the time of its discovery. Based on the robustness of the mandible and the size of the canine  
168 relative to the length of the cheek toothrow that reaches 42 %, GKZ-N 00001 is definitely a  
169 male. The horizontal ramus is long and thick, and has unparallel dorsal and ventral margins. The  
170 anterior border of the horizontal ramus (the portion anterior to the incisors and the canine) is  
171 expanded anterolaterally. The bone surface of the ramus is rough, but not vascularized. The  
172 mandibular symphysis is unfused, elliptical in shape, and upturned anteriorly. The posterior  
173 border of the symphysis extends below the anterior margin of p2. The genial tuberosity is very  
174 small and located below p3. There are eight distinct mental foramina on the lateral surface of the

175 horizontal ramus. They are nearly rounded or ellipsoidal in form, with the diameter varying from  
176 about 3 to 15 mm. The anterior mental foramen is located beneath i3 on the anterior margin of  
177 the horizontal ramus and is slit-like. Its length is about 15 mm and width is 4 mm. The middle  
178 mental foramina are located between p1 and p3 on the mid portion of the horizontal ramus, and  
179 the most anterior elliptical and large hole is located beneath p1 with the diameter of 11 mm in  
180 major axis and 6 mm in minor axis. The second middle mental foramen is located beneath p1 and  
181 p2 and rounded in outline, with a diameter of 11 mm. The third middle mental foramen is located  
182 beneath p2 on the mid portion of the horizontal ramus and is very large ellipsoidal in form. Its  
183 major axis is about 11 mm and minor is 6 mm. The fourth middle mental foramen is located  
184 between p2 and p3, and is rounded in outline and 6 mm in diameter. The fifth middle mental  
185 foramen is located between p3 and p4 and is rounded in outline and 7 mm in diameter. The sixth  
186 middle mental foramen is located beneath p4 and is the smallest rounded hole and 6 mm in  
187 diameter. The posterior mental foramen is located beneath the posterior margin of m1 and is the  
188 rounded in outline and 9 mm in diameter. Almost all of them are directed anterodorsally, but the  
189 fifth and sixth forward mental foramina are directed posterodorsally. Most of the coronoid  
190 process is broken away. The ventral margin of the masseteric fossa is preserved on the lateral  
191 surface and is relatively deep and large in area. It is anteroposteriorly broad at the base of the  
192 coronoid process. The pterygoid process is broken at the ventral margin on the medial surface of  
193 the ascending ramus. The mandibular foramen is large, with a diameter of 7 mm. The digastric  
194 prominence is very weak. The mandibular condyle is broken away, but the breakage suggests  
195 that it was elevated slightly high above the level of the cheek toothrow. The dentary has two  
196 incisors, one canine, four premolars and one molar. The dentition converges medially from p1  
197 until p3 and diverges laterally from p4 until m1. Each tooth is moderately spaced, and the  
198 diastema between the c1 and p1 is slightly wider than others.

199

200 **Teeth (Figs. 1, 2):** The i2 and i3 are missing, but their alveoli are preserved anterior to the c1.  
201 Both are single rooted. The c1 is robust and conical. Its apex is abraded. The pulp cavity of c1 is  
202 widely opened. The p1 is missing, but its alveolus is preserved on the dentary. It is single rooted.  
203 The p2 is preserved in place and lanceolate in form with sharp cutting edge. It has a highly  
204 developed lingual cingulum, and a well developed accessory cusp is located mesially at the base  
205 of the crown. The p3 is fallen away, but its alveolus is preserved, which is single rooted and  
206 bilobed in outline. The left and right p4 are preserved as detached isolated teeth. The crown is  
207 lanceolate with blunt cutting edge. It has poorly developed lingual cingulum with well developed  
208 accessory cusp. Their roots are bilobate and vertical to the long axis of the crown. The m1 is  
209 missing, but its alveolus indicates that the m1 is distinctly double rooted.  
210 The detached isolated P4 is preserved. The crown is tall and conical, and bluntly pointed at the  
211 tip with single cusp. There is no sharp cutting edge with a cingulum at the base of the crown.  
212 There is no well developed accessory cusp. It is bilobate single rooted, and its root is oblique to  
213 the long axis of the crown. The M1 is also preserved as a detached tooth. It has conical crown,  
214 blunt cutting edge, undeveloped cingulum, and slightly developed accessory cusp at the base of

215 crown. It is double rooted and oblique to the long axis of the crown. These roots are curved  
216 inward and forward strongly.

217

## 218 **Results of Morphometric analyses**

### 219 **Bivariate analyses**

220 GKZ-N 00001 is almost as large as the mandible of male Steller sea lion and larger than that of  
221 other known sea lions including the recently extinct Japanese sea lion and the middle Pleistocene  
222 Odysseus sea lion (Tables 2, 3, S1). In addition to the differences of their absolute sizes, the p1  
223 of the Odysseus sea lion is extremely smaller than other cheek teeth on the mandible (*Poust &*  
224 *Boessenecker, 2017*), and the consequent gradient of cheek tooth sizes against the cheek  
225 tooththrow length are quite different to that of GKZ-N 00001 and of the Steller sea lion. All these  
226 results rule out that GKZ-N 00001 belongs to the Odysseus and/or Japanese sea lions in size of  
227 the mandible and to the Odysseus sea lion in proportion of the cheek teeth. Given these  
228 differences, a taxonomic definition for GKZ-N 00001 as a species of *Eumetopias* is at least  
229 warranted. However, given the high amount of morphological variation within species of sea  
230 lions necessitates additional morphological approach to classify GKZ-N 00001 more clearly. For  
231 these reasons, we made morphometric analyses for GKZ-N 00001 with *E. jubatus* and at least all  
232 the North Pacific sea lions including extinct taxa mentioned above.

233 We performed 39 measurements among 21 landmarks on each mandible of 51 individuals from  
234 GKZ-N 00001 and extant taxa including 13 Northern fur seals and 24 Steller sea lions and  
235 extinct taxa including 11 Japanese sea lions and two Odysseus sea lions in total (Fig. 3, Tables 2,  
236 3, S1). These variables were correlated heuristically to each other. Then, highly correlated  
237 bivariate analyses were considered to evaluate taxonomic significance for the mandibular fossil. As the  
238 results of the analyses, three bivariate analyses by total of six parameters were distinctive among species;  
239 the depth of the horizontal ramus at c1 versus the mesiodistal diameter of c1, the depth of the  
240 horizontal ramus at p1 versus that of the same portion at m1, and the major axis of the  
241 mandibular symphysis versus the minor axis of the same portion (Fig.4). They were also  
242 distinctively differentiated between males and females. In all bivariate analyses, GKZ-N 00001 was  
243 plotted slightly larger than the 95% confidence interval of the Ordinary Least Square regression  
244 lines of the sampled male individuals of *E. jubatus*.

245 These results suggest that the difference between GKZ-N 00001 and the male *E. jubatus* is only  
246 a little and that the former could be included in the variation of the latter. In fact, the *E. jubatus*  
247 samples used in this study are individuals collected from around Hokkaido for a purpose to  
248 prevent damage to the fisheries, so the individuals tend to be slightly smaller in the average of  
249 their body size than that of the original population. For this reason, GKZ-N 00001 that is plotted  
250 slightly larger than the 95% confidence interval as *E. jubatus* could be interpreted as a large male  
251 individual of *E. jubatus*.

252

### 253 **Proportion of the canine root**

254 Regarding GKZ-N 00001, the greatest mesiodistal and buccolingual diameters of the lower  
255 canine root measured from CT image is 50.3 mm and 27.6 mm respectively (Fig. 5, Table 4).  
256 Accordingly, the ratio of the buccolingual to mesiodistal diameter expressed as a percentage is  
257 54.9. *Kohno & Tomida (1993)* suggested that the same ratio of the lower canines expressed as a  
258 percentage for the males of *E. jubatus* ranged from 51.6 to 61.8 (the mean is 56.6; Table 4).  
259 Therefore, GKZ-N 00001 is included within the range of male *E. jubatus* in regard to the canine  
260 proportion.

261

### 262 **Principal Component Analysis**

263 The measurement data from mandibles of GKZ-N 00001 with male and female individuals of *C.*  
264 *ursinus*, *Z. japonicus*, and *E. jubatus* were analyzed using PCA (Fig. 6). As a result of the  
265 analysis, the first principal component (PC1) explains the majority of the variation (~88.8 %),  
266 which represents variation of overall size. The larger individuals such as GKZ-N 00001 and male  
267 *E. jubatus* have negative scores, while smaller individuals such as female *C. ursinus* have  
268 positive scores. Sexual dimorphism can be observed in each taxon. There is only a little  
269 difference between GKZ-N 00001 and the sampled male individuals of *E. jubatus*. The second  
270 principal component (PC2) represents the proportion of the dorsoventral height and  
271 anteroposterior length of the mandible, meaning that the lower the PC2 value, the longer the  
272 mandible anteroposteriorly. It also means that the higher the PC2 value, the deeper the mandible  
273 dorsoventrally.

274

### 275 **Discussion**

276 GKZ-N 00001 has lanceolate, simplified cheek teeth, and lacks m2. This condition is recognized  
277 to be a synapomorphy of the crown Otariidae (*King, 1983; Boessenecker & Churchill, 2015;*  
278 *Velez-Juarbe, 2017*). In addition, the overall size of this mandible is included within the range of  
279 those in the largest sea lion; i.e., the Steller sea lion *E. jubatus*. Also a result of morphometric  
280 analyses for the size and proportion of the mandible for GKZ-N 00001 with extant species of a  
281 fur seal and sea lions such as the Northern fur seal, the Japanese sea lion and the Steller sea lion  
282 distributed in the western North Pacific suggest that GKZ-N 00001 is included in a range of *E.*  
283 *jubatus* and that it is inferred to be a male individual. Therefore, GKZ-N 00001 is distinctively  
284 identifiable to the extant species of the Steller sea lion *E. jubatus*. Although GKZ-N 00001 is  
285 slightly larger than male individuals sampled from the Recent population, it is at the moment  
286 uncertain whether this is simply the size variation among individuals of the same species or a  
287 potential implication of larger average size in the early Pleistocene population of the same  
288 species. At present, we consider that GKZ-N 00001 was just a large individual of *E. jubatus* until  
289 the multiple specimens of mandibles are obtained from the same and/or younger geochronologic  
290 formations.

291 Apart from the size difference, all the cheek teeth of the extant specimens of *E. jubatus* are single  
292 or bilobate single rooted. However, the alveolus for p4 of GKZ-N 00001 is bilobate single rooted  
293 in condition, and m1 is strongly bilobate and apically double rooted (Figs.7, S1). Although this

294 condition is not seen in the variation of extant specimens of *E. jubatus*, m1 root is always  
295 bilobate and its degree is strongly variable and successive among them (Fig. S1). Because the  
296 otariids (and stem taxa of odobenids in the Otarioidea) have a process that the cheek tooth  
297 condition is gradually changed from double rooted to single rooted to be homodont dentition  
298 during their evolution (Berta & Deméré, 1986; Boessenecker, 2011; Velez-Juarbe, 2018), the  
299 bilobate condition of p4 and the apically double rooted condition of m1 on GKZ-N 00001 are  
300 considered to be plesiomorphic conditions in a series of transition to the homodonty within a  
301 same species as a parallel phenomenon during their evolution. Accordingly, the condition of the  
302 cheek tooth roots on GKZ-N 00001 would also simply be a primitive feature for the lineage of  
303 the Steller sea lion.  
304 Finally, the recognition of GKZ-N 00001 as the oldest record of *Eumetopias jubatus* could also  
305 be important also for the molecular phylogenetics (see also Parham et al., 2012). Because only  
306 the subfamilial divergence estimates among the pinnipeds had calibrated based on fossil records  
307 of crown pinnipeds (e.g., Yonezawa et al., 2007), and because the oldest fossil record of  
308 *Eumetopias* had not been traced back only until the late Pleistocene, it could be considered the  
309 geologic age of GKZ-N 00001 as a good calibration point to improve divergence estimates  
310 between *Eumetopias* and its closest genus *Zalophus* and also of the crown Otariidae.

311

## 312 Conclusions

313 The mandibular fossil (GKZ-N 00001) from the lower Pleistocene Omma Formation (0.8 Ma) is  
314 specifically identified as *E. jubatus* based on the morphometric analyses. Previously, the oldest  
315 record of *E. jubatus* was from the upper Pleistocene of North America (Kohl, 1974; Whitmore &  
316 Gard, 1977; Barnes et al., 2006), so GKZ-N 00001 from the upper lower Pleistocene (ca. 0.8  
317 Ma) is now recognized as the oldest record of *E. jubatus*. This implies that the distribution of the  
318 Steller sea lion was already established at about by 0.8 Ma in the western North Pacific and at  
319 least southerly in the Sea of Japan.

**Table 3** (on next page)

Measurements (in mm) of GKZ-N 00001 for morphometric analyses

The numbers in parentheses correspond to each landmark.

rostral tip of mandible—ventral edge of mandible underneath the canine (1-5)	50.35
width of mandible (3-4)	42.76
depth of ramus at c1(5-21)	75.15
depth of ramus at p1(8-9)	76.46
depth of ramus at m1 (6-7)	66.34
ventral edge of mandible underneath the canine—ventral edge of mandible underneath the last postcanine (5-7)	100.13
lateral and caudal edge of last postcanine—rostral start point of the coronoid process (6-16)	27.60
major axis of mandibular symphysis	81.31
minor axis of mandibular symphysis	50.29
major axis of masseteric fossa	68.43
minor axis of masseteric fossa	45.73
depth of masseteric fossa	13.18
tooth length	123.89
cheek tooth length□	84.03
transverse width of c1	27.32
mesiodistal diameter of c1	35.00
anteroposterior length of p1	13.33
anteroposterior length of p2	12.79
anteroposterior length of p3	16.07
anteroposterior length of p4	14.51
anteroposterior length of m1	18.42
diastema length between c1 and p1	10.04
