Background. Climate plays a key role in the life histories of tropical vertebrates. However, tropical forests are only weakly seasonal compared with temperate and boreal regions. For species with limited ability to control core body temperature, even mild climatic variation can determine major behavioural outcomes, such as foraging and predator avoidance. In tropical forests, sloths are the arboreal vertebrate attaining the greatest biomass density, but their capacity to regulate body temperature is limited, relying on behavioural adaptations to thermoregulate. Sloths are largely or strictly nocturnal, and depend on crypsis to avoid predation. The harpy eagle (*Harpia harpyja*) is a sloth-specialist and exerts strong top-down control over its prey species. Yet the role of environmental variables on the regulation of predator-prey interactions between sloths and harpy eagles are unknown. The harpy eagle is considered Near Threatened. This motivated a comprehensive effort to reintroduce this species into parts of Mesoamerica. This effort incidentally enabled us to understand the prey profile of harpy eagles over multiple seasons. **Methods.** Our study was conducted between 2003 and 2009 at Soberanía National Park (SNP), Panamá. Telemetered harpy eagles were seen hunting and feeding on individual prey species. For each predation event, field assistants systematically recorded the species killed. We analysed the effects of climatic conditions and vegetation phenology on the prey species profile of harpy eagles using generalised linear mixed models.

Results. Here we show that sloth predation by harpy eagles was negatively affected by nocturnal ambient light (i.e. bright moonshine) and positively affected by seasonally cool temperatures. We suggest that the first ensured low detectability conditions for sloths foraging at night and the second posed a thermally unsuitable climate that forced sloths to forage under riskier daylight. We showed that even moderate seasonal variation in temperature can influence the relationship between a keystone tropical forest predator and a dominant prey item. So predator-prey ecology in the tropics can be modulated by subtle changes in environmental conditions. The seasonal effects shown here suggest important demographic consequences for sloths, which are under top-down regulation from harpy eagle predation, perhaps limiting their geographic distribution at higher latitudes.

24

25

26 **Abstract**

27 **Background.** Climate plays a key role in the life histories of tropical vertebrates. However,
28 tropical forests are only weakly seasonal compared with temperate and boreal regions. For
29 species with limited ability to control core body temperature, even mild climatic variation can
30 determine major behavioural outcomes, such as foraging and predator avoidance. In tropical
31 forests, sloths are the arboreal vertebrate attaining the greatest biomass density, but their capacity
32 to regulate body temperature is limited, relying on behavioural adaptations to thermoregulate.
33 Sloths are largely or strictly nocturnal, and depend on crypsis to avoid predation. The harpy
34 eagle (*Harpia harpyja*) is a sloth-specialist and exerts strong top-down control over its prey
35 species. Yet the role of environmental variables on the regulation of predator-prey interactions
36 between sloths and harpy eagles are unknown. The harpy eagle is considered Near Threatened.
37 This motivated a comprehensive effort to reintroduce this species into parts of Mesoamerica.
38 This effort incidentally enabled us to understand the prey profile of harpy eagles over multiple
39 seasons.

40 **Methods.** Our study was conducted between 2003 and 2009 at Soberanía National Park (SNP),
41 Panamá. Telemetered harpy eagles were seen hunting and feeding on individual prey species.
42 For each predation event, field assistants systematically recorded the species killed. We analysed
43 the effects of climatic conditions and vegetation phenology on the prey species profile of harpy
44 eagles using generalised linear mixed models.

45 **Results.** Here we show that sloth predation by harpy eagles was negatively affected by nocturnal
46 ambient light (i.e. bright moonshine) and positively affected by seasonally cool temperatures. We
47 suggest that the first ensured low detectability conditions for sloths foraging at night and the
48 second posed a thermally unsuitable climate that forced sloths to forage under riskier daylight.
49 We showed that even moderate seasonal variation in temperature can influence the relationship

50 between a keystone tropical forest predator and a dominant prey item. So predator-prey ecology
51 in the tropics can be modulated by subtle changes in environmental conditions. The seasonal
52 effects shown here suggest important demographic consequences for sloths, which are under top-
53 down regulation from harpy eagle predation, perhaps limiting their geographic distribution at
54 higher latitudes.

55

56

57 **Introduction**

58 Predation is a central theme in ecology and evolution, driving morphological, physiological, and
59 behavioural responses in prey species to the threat of death or injury (Genovart et al., 2010).
60 Both the nature and magnitude of predation as a dominant ecological force are affected by
61 seasonality (Darimont & Reimchen, 2002). However, the seasonality of predator-prey
62 relationships in tropical forests is at best considered to be subtle compared with temperate and
63 boreal regions, because of the comparatively low variation in day length and ambient
64 temperature (Forsythe et al., 1995). Nevertheless, tropical forests can experience considerable
65 seasonality in leaf flushing and fruiting as a response to climatic variables (Mendoza, Peres &
66 Morellato, 2016). While available data suggests that climatic conditions in tropical environments
67 have strong effects on animal activity (Foster et al., 2013; Cid, Oliveira-Santos & Mourão,
68 2015), there are relatively few studies about the nature of such effects on predator-prey
69 interactions.

70 Seasonally elevated rainfall and the resulting responses in vegetation growth can provide
71 food and cover for many arboreal taxa in tropical forests (Haugaasen & Peres, 2009).
72 Conversely, the dry season often induces leaf abscission in trees and woody lianas (Souza,
73 Gandolfi & Rodrigues, 2014), which may limit food availability and shelter to arboreal folivores.
74 The combination of reduced cover and limited food resource availability can enhance predation
75 risk (Menezes, Kotler & Mourão, 2014; Menezes, Mourão & Kotler, 2017). The seasonal
76 variation may modify the range of thermal microhabitats available to a prey species. As
77 endothermic forest specialists, sloths (genus *Bradypus* and *Choloepus*, order Pilosa) exhibit
78 relatively low basal metabolic rates and can only partially regulate body temperature (Pauli et al.,
79 2016). Therefore, they need to bask and can be affected by even mild variation in habitat cover
80 and thermally inappropriate microhabitats (Peery & Pauli, 2014; Giné et al., 2015), to the extent

81 that temperature seasonality is highly influential on sloth behavioural ecology (Moreira et al.,
82 2014).

83 Sloths from the *Bradypus* and *Choloepus* genus differ in their biology. *Choloepus* are
84 more vigorous (Pauli et al., 2016), larger (~6kg, Wetzel & Montgomery, 1985), have a higher
85 body temperature (Vendl et al., 2016), and a more diversified diet (Dill-McFarland et al., 2016).
86 *Bradypus* sloths fit the stereotypical sluggish behaviour of sloths (Pauli et al., 2016), are smaller
87 (~4kg; Wetzel & Montgomery, 1985), have a relatively low body temperature (Vendl et al.,
88 2016), and feed on leaves exclusively (Dill-McFarland et al., 2016). Finally, two-toed sloths
89 (*Choloepus* spp.) are nocturnal, whereas three-toed sloths (*Bradypus* spp.) are cathemeral
90 (Sunquist & Montgomery, 1973; Giné et al., 2015).

91 Likewise, moonlight is likely to alter animal behaviour by affecting detectability of both
92 predators and prey at night (San-Jose et al., 2019). Lunar phobia by mammals is widely justified
93 as a strategy to prevent predation (Cozzi et al., 2012). However, a metanalysis by Prugh and
94 Golden (2014) showed that the response to lunar light was typically idiosyncratic. While
95 visually-oriented mammals have an increased activity response to lunar light, mammals that have
96 weak vision—like sloths—generally decrease activity on bright nights (Prugh & Golden, 2014)
97 and therefore are less likely to suffer predation.

98 We can expected that the seasonality of predator-prey relationships involving sloths
99 might be affected by even subtle climatic fluctuations in ambient temperature. Sloths are
100 important prey species that rely heavily on crypsis to avoid predation, rather than evasive
101 responses once they are detected (Touchton, Hsu & Palleroni, 2002). However, studies
102 attempting to identify the cues leading to seasonal changes in prey activity and predation are
103 inherently hindered by small sample sizes. While apex predators have profound effects on

104 ecosystem structure and function (Terborgh et al., 2001), they are difficult to study, rendering
105 this lack of knowledge almost impossible to overcome.

106 The harpy eagle (*Harpia harpyja*; Fig 1) is considered Near Threatened by the IUCN
107 (Birdlife International, 2017), mainly because of human persecution (Muñiz-López, 2017) and
108 habitat loss, which have extirpated these mega-raptors from 41% of their former historical range
109 distribution (Miranda et al., 2019). Harpy eagles are an apex predator that specialises on sloths,
110 relying heavily on these prey species wherever they co-occur (Aguiar-Silva, Sanaiotti & Luz,
111 2014; Miranda, 2015). Harpy eagles hunt passively by visually scanning and listening to the
112 forest canopy (Touchton, Hsu & Palleroni, 2002). They are unique among eagles having a large
113 retractable facial disc to enhance their hearing (Ferguson-Lees & Christie, 2001). Harpy eagles
114 are the Earth's largest eagles. Being large-sized, they can prey on sloths of any age (Aguiar-
115 Silva, Sanaiotti & Luz, 2014), including adult individuals of all continental sloth species
116 (Miranda, 2018). Harpy eagle-sloth predator-prey systems are therefore ideal candidates to
117 investigate how changes in climate and moonlight may affect multispecies predation rates.
118 The Peregrine Fund has lead a comprehensive effort to reintroduce this species into parts of
119 Mesoamerica (Campbell-Thompson et al., 2012; Watson et al., 2016). This effort, spanning from
120 2003 to 2009, incidentally enabled us to understand, for the first time, the prey profile of harpy
121 eagles over multiple seasons.

122 We explored environmental determinants of prey capture rates of reintroduced harpy
123 eagles in Soberanía National Park; a tropical protected area in Panamá. Our goals were twofold:
124 (1) to assess the effects of seasonality—like temperature, rainfall and leaf deciduousness—on
125 sloth capture rates by harpy eagles; and (2) to assess how moonlight could affect sloth and
126 nocturnal prey predation rates. We predicted that: (1) sloth predation rates would increase with

127 low temperatures, high rainfall and low leaf cover; (2) sloth and nocturnal prey predation rates
128 would increase with low moon brightness.

129

130 **Materials & Methods**

131 **STUDY SITE.** — Our study was conducted between 2003 and 2009 at Soberanía National Park
132 (hereafter, SNP), a 19,545 ha protected area in eastern Panama along the banks of the Panama
133 Canal (9°07'13" N, 79°39'37" W). The vegetation of SNP consists of semi-deciduous,
134 seasonally moist tropical forest, most of which is now advanced (>80 years) secondary forest
135 (Bohlman, 2010). The area has most of the staple prey species targeted by harpy eagles (Aguiar-
136 Silva, Sanaiotti & Luz, 2014), including three-toed sloths (*Bradypus variegatus*), Hoffman's
137 two-toed sloths (*Choloepus hoffmanni*), white-nosed coati (*Nasua narica*), northern lesser
138 anteater (*Tamandua mexicana*) and mantled howler monkeys (*Alouatta palliata*), all of which are
139 either strictly arboreal or scansorial mammals. The Peregrine Fund had conducted experimental
140 harpy eagle releases within SNP since 1997 (Muela et al., 2003; Watson et al., 2016), therefore
141 we assumed that none of the prey species here were predator-naïve during our study.

142 The SNP has a marked dry season from December to April and a wet season from May to
143 November. The wet season concentrates 85.3% of the annual rainfall, which averaged 2,242 mm
144 p.a. for 2003-2009. During the dry season, the mean, minimum and maximum ambient
145 temperatures were 27.3, 22.1, 33.0°C, respectively, and slightly warmer than the corresponding
146 temperatures during the wet season (26.5, 23.2, 30.9°C, respectively). Daily climate data were
147 obtained from ETESA (<http://www.hidromet.com.pa/>), using Hodges Hill Meteorological Station
148 data for rainfall (15 km from the release site) and the Tocumen Station for data on temperature

149 (43 km from the release site). A Walter-Lieth climate diagram describing the seasonality of
150 rainfall and ambient temperature in the park was created (Supplementary Information Fig. S1).

151 HARPY EAGLE PREY PROFILE.—Before final release, captive-bred harpy eagles were soft-
152 released at SNP by a process known as hacking (Muela et al., 2003). This allowed harpy eagles
153 to learn how to hunt, as would occur in the wild (Muñiz-López et al., 2016). Further details on
154 the harpy eagle reintroduction protocols and results are available in Campbell-Thompson et al.
155 (2012) and Watson et al. (2016). Harpy eagles were fitted with both radio-telemetry and GPS
156 tags. During soft releases, they were fed thawed rats and rabbits, always using a blind to avoid
157 food conditioning with humans. Foraging independence was defined on the basis on an eagle
158 being able to make two unassisted successive kills within 20 days or survive 30 days without
159 food provisioning, thereby demonstrating that it was able to hunt self-sufficiently. Both regular
160 radio- and global position system (GPS)-tracking leading to visual contact with each telemetered
161 eagle was required to check its body condition.

162 As the reintroduced harpy eagles were captive-born sub-adults (5-22 months; Campbell-
163 Thompson et al., 2012) from captive stock maintained by The Peregrine Fund, we performed an
164 *a priori* graphical analysis to ensure that the diet of reintroduced harpy eagles was similar to that
165 of wild adult individuals. We did so by dividing the number of captured prey items within blocks
166 of 25 samples (which adequately represents the main prey species; Miranda 2015) and
167 distributed them according to ontogeny or experience. We defined ontogeny as age in months for
168 any given predation event, whereas we defined experience as any given predation event relative
169 to the number of days since the first wild prey item was captured. Neither ontogeny nor
170 experience affected harpy eagles' patterns of predation as there was no evidence of nested
171 patterns that would be expected if shifts in prey preferences occurred (Supplementary

172 information Fig. S2 and S3). We therefore consider hunting patterns by reintroduced harpy
173 eagles comparable with those of wild adults, and this was consistent with previous reports
174 (Touchton, Hsu & Palleroni, 2002). The spatial distribution of those kill sites, as well as the
175 location of the release site and meteorological stations within SNP are shown in Fig. 2.

176 PREDATION AND ENVIRONMENTAL DETERMINANTS.— During observations, while tracking,
177 harpy eagles were seen hunting and feeding on individual prey species. For each predation event,
178 field assistants systematically recorded all species killed (whenever identification to the level of
179 species was possible). Field assistants were instructed to remain as inconspicuous as possible
180 and leave the eagles alone as soon as observations were recorded. Prey items of known species
181 identity were recorded during all months of the year, over the 7-year study, although
182 observations were typically sparser during the month of November.

183 We related measures of climatic seasonality and vegetation phenology to the prey species
184 profile of harpy eagles. Daily climatic data on precipitation and ambient temperature, were
185 obtained from nearby meteorological stations. Data on the phases of the lunar cycle at a daily
186 resolution over the entire study period were obtained from <http://www.astronomyknowhow.com>.
187 We used the percentage of moon shade cover per night as a proxy for light availability. We used
188 the normalised difference vegetation index (NDVI) as a proxy for canopy leaf deciduousness,
189 where $NDVI = (IR - R)/(R + IR)$, IR being the near- infrared LANDSAT band 4 and R the red
190 LANDSAT band 3. NDVI values were calculated using georeferenced LANDSAT images obtained
191 for all months of the year during the study period. NDVI is a measure of vegetation ‘greenness’,
192 rather than deciduousness, but is highly correlated to leafing cycles (Bohlman, 2010). For each
193 prey detection event, we estimated the NDVI score of all 30 m x 30 m pixels within a 1 km
194 radius of the location of each predation event for the nearest five dates of LANDSAT images

195 available for that period. We then interpolated these indices to estimate the composite NDVI
196 metric for the detection date of each prey item.

197 We ran two batches of generalised linear mixed-effects models (GLMM) using as
198 response variables (1) the probability of any given prey item being a sloth (either *Bradypus* or
199 *Choloepus*) and (2) the probability of any given prey item being nocturnal. Because the set of
200 environmental covariates for each model was large, we used a backwards AIC-based stepwise
201 algorithm to select the most important variables for each fixed-effect model, adding the random
202 effect afterwards. All GLMMs were run using a binomial error structure and the logit link
203 function, and bird identity as a random effect on the intercept. All variables used were checked
204 for covariance using the Variance Inflation Factor (VIF). All analyses were run using the R 3.6.1
205 platform. Environmental covariates used in each GLMM are presented in Supplementary
206 information Table S1. All source codes used in the analyses are available at
207 <https://github.com/KenupCF/HarpySlothPredation>.

208 The Peregrine Fund Harpy Eagle Restoration Program complied with the laws of Panamá
209 during the time in which the project was performed, with permits granted by National
210 Environmental Authority of Panama (ANAM, at present MiAmbiente and SISBIO#58533-5).
211

212 **Results**

213 We recorded a total of 200 harpy eagle predation events, from which we obtained positional data
214 for 189 prey items, 173 of which were identified. These prey items were killed by 33 harpy
215 eagles during six dry seasons and six wet seasons during the 7 years of study. This amounted to
216 88 prey samples during the dry seasons and 85 samples during the wet seasons. The temporal
217 distribution of predation records and the functional groups of prey species showed that sloths

218 were by far the most important prey species for harpy eagles (Fig. 3). Two sloth species
219 represented 65.3% of the harpy eagle diet in terms of the overall numeric prey profile, of which
220 brown-throated sloths, Hoffman's two-toed sloths and unknown sloths represented 34.1%, 15.6%
221 and 15.6% of all prey items, respectively. Second to sloths, the next most significant dietary
222 contributors to harpy eagles were white-nosed coatis (7.5%), northern lesser anteaters (6.9%) and
223 mantled howler monkeys (5.2%). Further information on the prey species composition are shown
224 in Table 1.

225 Sloth predation rates increased significantly during low moon brightness ($\beta = -0.648$, $p =$
226 0.0116) and low ambient temperatures with marginal statistical significance ($\beta = -0.508$, $p =$
227 0.0535 ; Fig. 4). Harpy predation on nocturnal animals was weakly affected by low moon
228 brightness (Fig. 4), but this lacked sufficient statistical significance ($\beta = -0.392$, $p = 0.1461$).
229 Rainfall and leaf deciduousness had no discernible effect in any of our models. Statistical results
230 are summarised in Table 2.

231

232 Discussion

233 Although environmental conditions either increase prey vulnerability or provide an advantage to
234 sit-and-wait and pursuit predators (Doody, Sims & Letnic, 2007; Prugh & Golden, 2014), little
235 has been documented on this topic in closed-canopy tropical forest ecosystems. In harpy eagle-
236 sloth predator-prey systems, we showed increases in sloth nocturnal activity under elevated
237 moon brightness and cryptic behaviour during the day provided mechanisms of escaping
238 detection by harpy eagles. We also showed an increase in predation rates under cool
239 temperatures, which may induce further diurnal activity of sloths. Finally, we examined the roles
240 of leaf flush and rainfall on harpy eagle prey choice, but neither had a detectable effect on sloth
241 predation rates. These results pose interesting questions about the consequences of temperature
242 and moon brightness to this keystone Neotropical forest predator and its dominant prey species.

243 Moonlight has been shown to have contradictory effects on nocturnal mammal activity
244 patterns in terms of their antipredator strategies. Prey species that can detect predators visually
245 and anticipate their attacks with evasive maneuvers may increase foraging activity under high
246 levels of moonlight, whereas those that cannot decrease activity (Prugh & Golden, 2014). Sloths,
247 however, typically prefer to sleep at night in environments where they evolved with predator
248 presence (Voirin et al., 2014), and in other areas generally showing greater fear of diurnal
249 predators as harpy eagles. Indeed, there is anecdotal evidence of increased sloth activity during
250 full moon phases (Beebe, 1926). Sloths are known to be lethargic and have extremely poor
251 vision, while harpy eagles typically attack from distances of less than 30 m during daylight
252 (Touchton, Hsu & Palleroni, 2002). We, therefore, expected that sloths reduce their overall
253 activity during the day, instead foraging at night under bright moonlit to reduce predation risk,
254 which significantly reduces the probability of successful attacks by diurnal harpy eagles. Success

255 rates of harpy eagles predation on sloths is generally high compared with visually oriented prey:
256 55% of all attacked sloths are successfully killed, while only 33% of visually oriented prey are
257 successfully killed if they had been attacked (Touchton, Hsu & Palleroni, 2002). This may be the
258 underlying adaptive reason why sloths are inactive during the day if bright nights are available as
259 foraging time, neutralising search images of diurnal predators and greatly reducing their
260 detection probability by harpy eagles. Further sloth telemetry studies would provide
261 confirmatory evidence.

262 In addition to the reduced predation levels of sloths during bright moon nights, we
263 showed that as ambient temperatures increased, predation rates declined. Presumably, this
264 happened because of the increased daytime activity levels of this endotherm, which is prone to
265 metabolic torpor under cooler weather conditions, especially at night (Giné et al., 2015). It has
266 been shown, for instance, that the nocturnal activity of the maned sloth (*Bradypus torquatus*) is
267 inhibited by lower ambient temperatures (Chiarello, 1998). Predation rates of sloths by harpy
268 eagles were higher during colder conditions, which likely induce compensatory activity by sloths
269 during the warmer daytime. Basking behavior of sloths increases with lower ambient
270 temperatures along altitudinal gradients in mountainous areas (Urbani & Bosque, 2007). Another
271 possible explanation for the temporal changes in sloth predation rate could result from its
272 reproductive behaviour. However, the literature shows weak and idiosyncratic evidence for
273 seasonal breeding for both sloth species present in our study area (Taube et al., 2001). These
274 features reinforce our premise that behavioural crypsis is the main antipredator strategy of sloths,
275 which we suggest to be the underlying reasons for the patterns observed in our study. Indeed, the
276 latitudinal boundaries of the geographic distribution of sloths are far more restricted than those of
277 harpy eagles (Moreira et al., 2014; Miranda et al., 2019). Sloths of the *Choloepus* genus are

278 distributed over tropical Central America and the pan-Amazonian region, while *Bradypus* also
279 occur over the northern section of Atlantic Forest (Emmons & Feer, 1997). Predation by harpy
280 eagles may play a key role in limiting sloth geographic distribution—and altitudinal ranges—
281 given that sloths would be required to compensate for cooler temperatures in the southern
282 Atlantic Forest or higher regions by increasing levels of diurnal activity (Chiarello, 1998; Urbani
283 & Bosque, 2007). Therefore, this would inhibit extended periods of inactivity induced by cool
284 temperatures, but increase temporal activity overlap with diurnal predators.

285 Rainfall apparently had no effect in any of our models explaining the incidence of sloth
286 predation, a pattern that could also be explained by low predation risk resulting from the
287 cessation of harpy eagle activity during rainy weather (Touchton, Hsu & Palleroni, 2002), or
288 even distance from the meteorological stations, inducing error. Leaf abscission presented no
289 effects on predation of sloths. Although we predicted increased probability of arboreal prey
290 detection under leafless conditions in the semi-deciduous forests of central Panama, forest areas
291 dominated by leafless trees and/or woody lianas may be consistently avoided by prey species
292 relying on concealed foraging activity (Menezes, Kotler & Mourão, 2014; Menezes, Mourão &
293 Kotler, 2017). For a sloth, leafless tree crowns offer little if any protective cover and no food
294 resources. Our robust methods to estimate levels of deciduousness combined with a wide buffer
295 describing the likely sight range of potential kills suggest that arboreal habitats lacking foliage
296 cover would be avoided not only by prey species but also by harpy eagles, thereby at least partly
297 explaining why deciduousness had no effects in any of our models.

298 Nocturnal prey capture by harpy eagles was not significantly affected by any of the
299 environmental covariates, and the fact that these large diurnal raptors can frequently successfully
300 kill several strictly nocturnal prey species remains puzzling. Modest increases in predation rates

301 of nocturnal mammals were associated with darker nights, when nocturnal species typically
302 preyed by harpy eagles (anteaters, opossums, and armadillos) are expected to be more active
303 given their poor ability to anticipate incoming predators visually (Caro, 2005; Prugh & Golden,
304 2014). The harpy eagle sit-and-wait predation strategy is further enhanced by their retractable
305 facial disc, which performs the same function as in strictly nocturnal raptors (i.e. owls), of
306 improving acoustic detection of prey. Combined with extremely acute vision, which is likely
307 associated with a high density of photoreceptor cells in the retina typical of many diurnal raptors
308 (Lisney et al., 2013), harpy eagles are superbly capable of locating inconspicuous prey, enabling
309 them to be the only Neotropical apex predator to specialise on the highly secretive sloths
310 (Miranda, 2015; Miranda, Menezes & Rheingantz, 2016). Harpy eagle activity patterns can be
311 investigated with further research using either intensive telemetry-assisted follows or camera
312 trapped nests. By including nocturnal telemetry or motion-sensitive telemetry devices on
313 monitoring schedules or confirming that harpy eagles can deploy crepuscular/nocturnal hunting
314 effort at the time of nesting (e.g. evidenced by nocturnal prey delivery) would largely solve this
315 question.

316 Our results suggest important consequences for patterns of prey mortality through the
317 tropical seasons of Neotropical forests. We, therefore, suggest that researchers, conservationists
318 and practitioners can learn from natural fluctuations in predator-prey systems when designing
319 management actions (such as reintroduction, release and translocation efforts) of both harpy
320 eagles and their prey, since some of these prey species are also threatened (Catzeflis et al., 2008;
321 Moreira et al., 2014; Suscke et al., 2016). For instance, consequences of the harpy eagle
322 reintroduction on the endemic maned sloth which is listed as Vulnerable in the Brazilian Atlantic
323 Forest needs careful evaluation.

324

325 Conclusions

326 We showed that the probability of harpy eagles preying on sloths decreased in response to
327 nocturnal high moon brightness and increased with low temperatures. This almost certainly
328 occurs because sloths respond to low temperatures foraging more in the daytime, and circumvent
329 high diurnal detectability by foraging on bright moonlit nights when they are not exposed to
330 visually oriented predators. These conceptually simple conclusions result from overcoming the
331 formidable challenges of monitoring the diet of apex predators in tropical forests for extended
332 periods. We further note that the seasonal effects we uncovered here suggest important
333 consequences for herbivore prey species, whose populations are likely regulated by top-down
334 predation from harpy eagles and other top predators. The magnitude of cyclic changes in
335 predator-prey interactions shown here potentially are even stronger in more seasonal tropical
336 and subtropical forests experiencing cooler seasons, higher altitudes or prolonged flood pulses.
337 Further studies on a diverse set of predator and prey assemblages in tropical forests elsewhere
338 would help fill this knowledge gap.

339

340 Acknowledgements

341 We thank the many institutions and staff who have participated in The Peregrine Fund's Harpy
342 Eagle Restoration Program. We also thank hack-site attendants for field assistance. Everton
343 Miranda's logistical support was given by the Peugeot-ONF Carbon Sink Reforestation Project,
344 based at the São Nicolau Farm in Cotriguaçu, Mato Grosso, Brazil. This Project is a Peugeot
345 initiative to fulfil some of the Kyoto Protocol directions and is run by the ONF-Brasil enterprise.

346 CTD is grateful to the University of KwaZulu-Natal (ZA) and the National Research Foundation
347 (ZA) for funding. Marcus Canuto, Jose Vargas and Alexander Blanco provided useful
348 discussions, improving a previous version of the manuscript. The Peregrine Fund Harpy Eagle
349 Restoration Program complied with the laws of Panamá during the time in which the project was
350 performed. We are grateful for the constructive comments of Mario Fernando Garces Restrepo
351 and an anonymous reviewer.

Figure 1

Fig. 1. Harpy eagle preying over sloth.

Adult female harpy eagle (*Harpia harpyja*) eating a young Two-toed sloth (*Choloepus didactylus*; Photo: Danilo Mota).

Figure 2

Fig. 2. Study site.

Location of Soberanía National Park in central Panama (lower left inset map), showing the location of 189 predation events (green dots), release site (white star) and meteorological stations (white triangles).

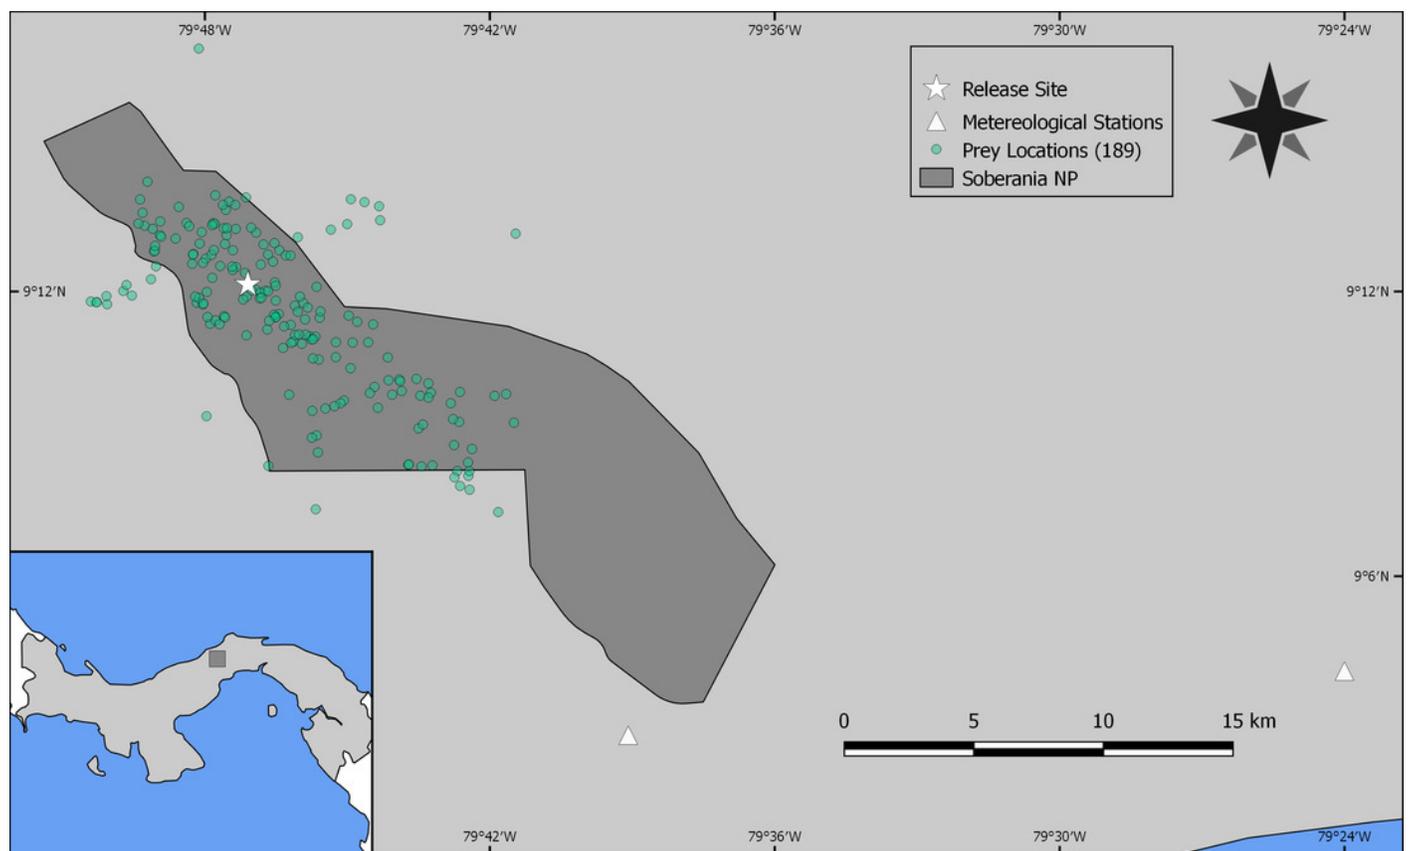

Figure 3

Fig. 3. Prey composition and effort.

Monthly distribution of harpy eagle kills throughout the year. Vertical bars are color-coded according to the main prey functional groups. Observations were made in all months of the year, however more scantily in November.

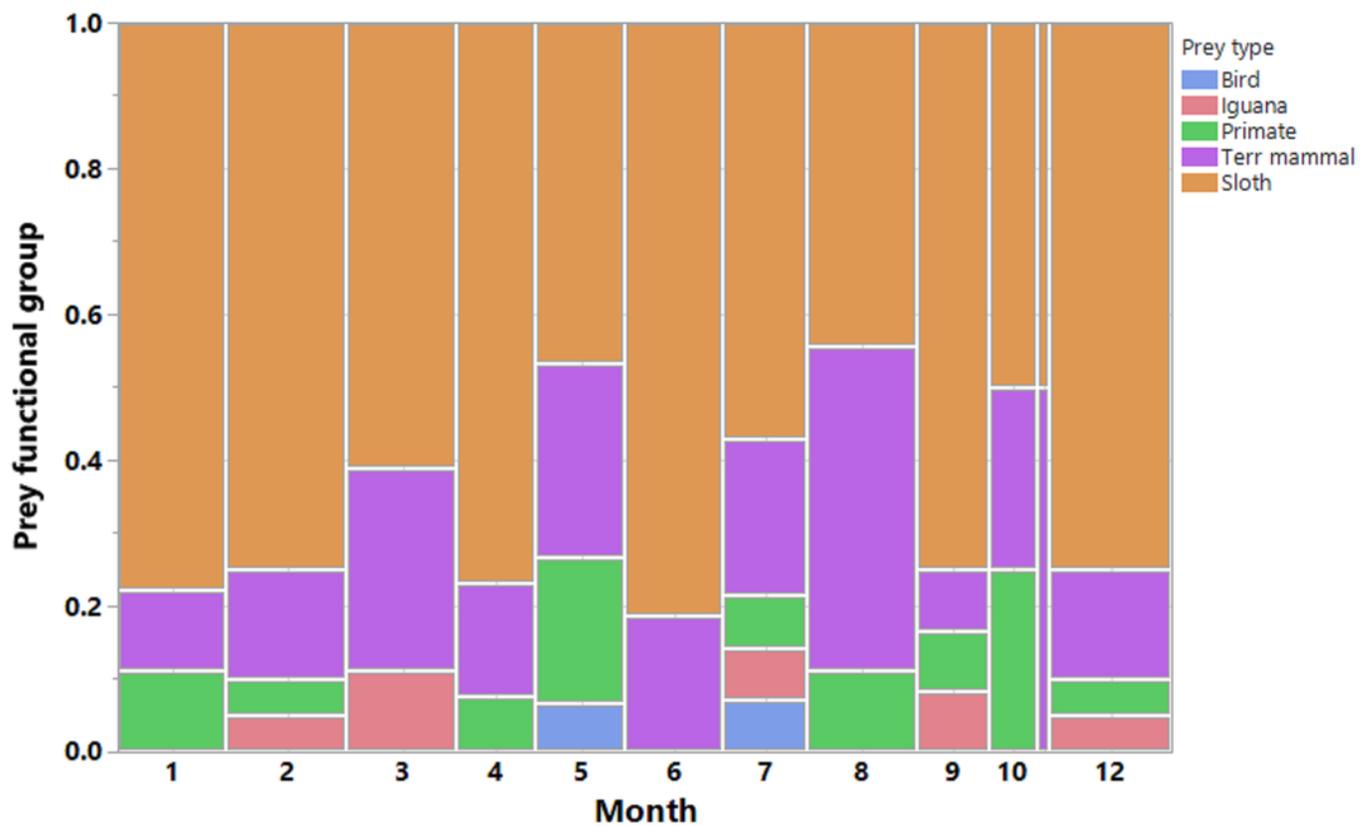

Figure 4

Effect of environmental variables on the probability of predation events by harpy eagles.

A - Effect of moon brightness on sloth predation probability: fewer sloths were taken during bright moonlit nights ($p = 0.0134$). B - Effect of minimum temperature on sloth predation probability: fewer sloths were taken under cooler conditions ($p = 0.0413$). C - Effect of moon brightness on nocturnal mammal predation: fewer nocturnal prey were killed during bright nights, but this lacked statistical significance ($p = 0.12$).

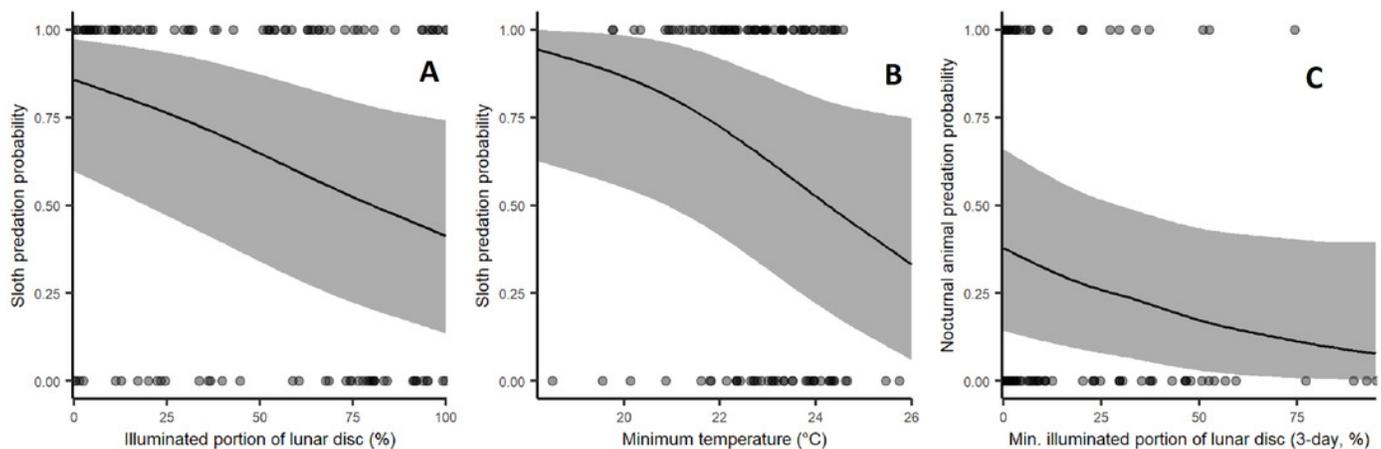

Table 1 (on next page)

Table 1. Prey composition in the diet of harpy eagles.

Seasonal changes in incidence of kills by harpy eagles shown in percentages, combining frequencies for both wet and dry seasons across the seven years of study (2003 – 2009). Overall column shows percentages of prey items for all periods combined, and sample sizes (in parentheses). See “Study Site” section of Methods for further details of season definition.

Table 2 (on next page)

Table 2. Results of generalized linear mixed models of harpy eagle prey profile.

First model predicts probability that a given animal preyed by a harpy eagle is a sloth, while the second model predicts probability of prey being a nocturnal animal. Both models use a logit link due to the binomial nature of the data. Both models use tracked individuals and years sample as random effects over the intercept.

1 **Table 2. Results of generalized linear mixed models of harpy eagle prey profile.** First model
 2 predicts probability that a given animal preyed by a harpy eagle is a sloth, while the second model
 3 predicts probability of prey being a nocturnal animal. Both models use a logit link due to the
 4 binomial natural of the data. Both models use tracked individuals and years sample as random
 5 effects over the intercept.

Model	Variable	Estimate	Standard Error	p-value	Random Individual Variance	Random Yearly Variance
	Intercept	0.588	0.470	0.2109	1.001	0.513
Sloth	Lunar disc (%)	-0.648	0.257	0.0116	-	-
	Minimum temperature (°C)	-0.508	0.263	0.0535	-	-
