# Abstract

**Background.** Sub-cellular compartmentalization is used by cells to create favorable microenvironments for various metabolic reactions. These compartments concentrate enzymes, separate competing metabolic reactions, and isolate toxic intermediates. Such advantages have been recently harnessed by metabolic engineers to improve the production of various high-value chemicals via compartmentalized metabolic engineering. However, measuring sub-cellular concentrations of key metabolites represents a grand challenge for compartmentalized metabolic engineering.

**Methods.** To this end, we developed a synthetic biosensor to measure a key metabolite, acetyl-CoA, in a representative compartment of yeast, the peroxisome. This synthetic biosensor uses highly efficient enzyme re-localization via PTS1 signal peptides to construct a metabolic pathway in the peroxisome, which converts acetyl-CoA to polyhydroxybutyrate (PHB) via three enzymes, phaA phaB and phaC. The PHB is then quantified by HPLC.

**Results.** The biosensor demonstrated the difference in relative peroxisomal acetyl-CoA availability under various culture conditions and was also applied to screening a library of single knockout yeast mutants. The screening identified several mutants with drastically reduced peroxisomal acetyl-CoA and one with potentially increased levels. We expect our synthetic biosensors can be widely used to investigate sub-cellular metabolism and facilitate the “design-build-test” cycle of compartmentalized metabolic engineering.

# Introduction

Sub-cellular compartmentalization is used by all eukaryotes and some prokaryotes as a means to create favorable micro-environments for various metabolic reactions. These compartments concentrate enzymes and substrates(Choi & Montemagno, 2006), increasing efficiency. Compartmentalization also helps to keep incompatible pathways separate(Zecchin et al., 2015) and can provide a safe area for toxic intermediates. Recently, metabolic engineers have explored the concept of pathway compartmentalization to enhance the performance of metabolic pathways(Avalos, Fink & Stephanopoulos, 2013; Zecchin et al., 2015; Zhou et al., 2016).

One challenge to the continued progress of compartmentalized metabolic engineering is the lack of tools for measuring local metabolite concentrations at a sub-cellular scale. There are many proprietary colorimetric and fluorescent assays (such as glucose peroxidase assays(Ngo & Lenhoff, 1980) or enzymatic acetyl-CoA assays(Fritz et al., 2013)) but these *in vitro* methods often require cell lysis. Cell fractionation involves separating cell compartments of interest beforehand, but contamination with similarly sized organelles is possible following differential or density gradient centrifugation(Kikuchi et al., 2004). *In vivo* biosensors are another popular method for screening the response of metabolites to various perturbations. This technique often involves the use of transcription factors that recognize the analyte and activate bioluminescence or fluorescence reporter genes(Michener et al., 2012; Mustafi et al., 2012; Broгнаux et al., 2013; Li & Yu, 2015; Mahr et al., 2016; Skjoedt et al., 2016). This, generally, means that the detection of the analyte largely occurs in the cytoplasm or nucleus.

To provide a tool for measuring metabolite availability in sub-cellular compartments, we propose using a localized synthetic biosensor as a form of metabolic assay. In this method, heterologous enzymes are expressed with localization tags to produce some reporter compound only in the compartment of interest. With high levels of enzyme expression, we hypothesize that the production of the reporter compound will be rate-limited by the substrate concentration, allowing for relative quantification of the substrate. The reporter compound can then be extracted from the cell and quantified. Here, we showcase the use of one such synthetic biosensor to measure acetyl-CoA in the peroxisomes of the yeast *Saccharomyces cerevisiae*. Acetyl-CoA is a core metabolite whose availability has implications in many important metabolic pathways. Measuring total, cellular acetyl-CoA levels is a simple matter using commercially available enzymatic assay kits(Jose & Suraishkumar, 2016), but measuring acetyl-CoA in organelles is more challenging since conventional assays would require the organelles to first be isolated by cell fractionation. Polyhydroxybutyrate (PHB) production can also be used as an indirect marker of acetyl-CoA availability. Only three enzymes are needed for the conversion of acetyl-CoA into PHB(Wang & Yu, 2007) and they can be efficiently localized to the peroxisome by inclusion of C-terminal PTS1 peptide tags(Kim & Hettema, 2015). Acetyl-CoA does not readily cross membranes(Chen, Siewers & Nielsen, 2012), so the peroxisome-localized enzymes should only

have access to the peroxisomal pool of acetyl-CoA (*Fig. 1*). In this paper, a localized enzymatic assay and HPLC analysis of the cellular PHB content were used to qualify the response of acetyl-CoA in the peroxisome to several culturing conditions and gene knockout perturbations.

## Materials and methods

### Media and strains

Minimal media was prepared as previously reported (Blank & Sauer, 2004; Guo et al., 2016) with a glucose concentration of 0.5% w/v. Yeast nitrogenous media YN contains 0.67% w/v yeast nitro base, 0.1% yeast extract and 0.5% glucose. Synthetic complete media contained 0.17% yeast nitro base, 0.5% ammonium sulfate, 0.5% glucose and 1x CSM Ura supplement from MP biomedical. All cultures were incubated at 30°C in a shaking incubator. The experiment testing for the effect of media composition used 10 mL cultures each and the mutant screening cultures were 3 mL cultures each from which only 2 mL was harvested at the end of culturing. The growth/production curve experiments used 20 mL cultures from which 2 mL were drawn at each time point. All of the homologous recombinations were performed in *Saccharomyces cerevisiae* Invitrogen strain INVSc1. Plasmids were transferred to *E. coli* strain Top10 for verification and long-term storage. All cultures used to collect and measure PHB were performed in *Saccharomyces cerevisiae* strain BY4741 or BY4741-derived single gene knockouts.

### Cloning

All plasmids, strains, and primers are shown in Supplementary Methods *Table S1*. The three *pha* genes were codon-optimized for yeast and kindly provided by Jens Nielsen (Kocharin et al., 2012). Construction of the plasmids pPHBc and pPHBp was accomplished by an established, yeast homologous recombination-based method, DNA assembler (Shao & Zhao, 2009). Briefly, DNA fragments were amplified by PCR using primers that add homologous overlap between adjacent fragments. The fragments were then co-transformed into *S. cerevisiae* along with a linearized backbone to assemble elements in a single step (Shao, Luo & Zhao, 2011). Gene fragments used to construct plasmid pPHBp used modified primers for the addition of PTS1 localization tags (Liu & Naismith, 2008). Additional details are provided in the Supporting Information.

### HPLC analysis

Culture samples of 10 mL were centrifuged at 4000 rpm for five minutes, and rinsed twice with 10 mL of ddH<sub>2</sub>O. Pellets were then dried for 48 hours at 70°C. PHB is insoluble, so it is regularly converted to crotonic acid monomers by sulfuric acid digestion (Karr, Waters & Emerich, 1983). The pulverized dry pellets (or thin films for smaller samples) were digested with 100 µL of

concentrated H<sub>2</sub>SO<sub>4</sub> per mL of the pre-dried sample. Acid digests were carried out at 95°C for 1 hour. The digest was diluted with 400 µL of ddH<sub>2</sub>O for every 100 µL of acid used. The carbonified cell debris was removed by centrifugation at 13,000 rpm for 10 min. These samples were analyzed by HPLC with an Aminex HPX-87H ion exclusion column with a temperature of 60°C and a flow rate of 0.6 mL min<sup>-1</sup> and with 5 mM H<sub>2</sub>SO<sub>4</sub> as the mobile phase.

## Results

### Dependence on fatty acids

To test the viability of the localized synthetic biosensor, a proof-of-concept study was performed in which yeast cells with PHB-producing genes (with or without peroxisomal localization) were analyzed to compare acetyl-CoA levels in the cytosol and peroxisome. PHB production was achieved by expressing three enzymes from *Ralstonia eutropha* H16. The first enzyme (*phaA*) consumed two acetyl-CoA to produce acetoacetyl-CoA. The next enzyme (*phaB*) reduced the acetoacetyl-CoA in order to generate 3-hydroxybutyryl-CoA monomers. The monomers were then polymerized by the final enzyme (*phaC*) (Wang & Yu, 2007). These genes were previously codon-optimized for use in yeast cells (Kocharin et al., 2012). All three genes were combined in each of two plasmids. Plasmid pPHBc contained the codon-optimized genes without peroxisomal localization and thus the enzymes end up in the cytoplasm. Plasmid pPHBp contained the same three enzymes with high efficiency peroxisomal localization tags (DeLoache, Russ & Dueber, 2016) added by homologous recombination (Joska et al., 2014). We chose PHB as our reporter compound because of the following two considerations. First, PHB is detected relatively easily and is non-native to yeast cells. Therefore, the PHB signal is representative of peroxisomal acetyl-CoA concentration. Second, the PHB pathway is relatively short, with only three enzymes, which reduces the risk of metabolic burden.

To validate our hypothesis that peroxisomal acetyl-CoA could lead to PHB production, we cultured the peroxisomal and cytosolic variants of the PHB producing strains (phbP and phbC respectively) in various media with various concentrations of oleic acid for 48 hours. Three media were used: synthetic complete yeast media (SC), minimal media, and yeast nitro base (YN) media. Oleic acid content ranging from 0%, 0.2% and 0.5% w/v was added into each of the media. The cytosolic *pha* genes were able to produce similar levels of PHB with any of the media and at all of the oleic acid concentrations present (Fig. 2A). No PHB was produced by the peroxisomal strain phbP when oleic acid was absent from the media (Fig. 2B). Also, we found that with the increase of oleic acid concentration in the YN media, the PHB production also increased.

### Growth and production curves

Both strains were then cultured in YN media with 0.5% oleic acid and sampled periodically until PHB production plateaued (*Fig. 3*). Strain phbC achieved a maximal PHB level of around 30 mg/g DCW within only 24 hours, which was the same amount of time it took to achieve a maximum cell density (~5 O.D.). Strain phbP reached the same cell density in those 24 hours, but only started producing PHB after that point. PHB production in the phbP strain reached a maximum of about 7 mg/g DCW after five days.

## Knockout screening

We demonstrated the application of our compartmentalized biosensor by screening several mutants for altered levels of peroxisomal acetyl-CoA. In brief, thirteen yeast single knockout mutants were selected and transformed with pPHBp. Three of the genes, *adr1*, *aat2* and *ino1* are transcription factors that promote fatty acid synthesis or fatty acid utilization. Three of the genes, *rpd3*, *opi1* and *sin3* are transcription factors that repress fatty acid synthesis. The genes *pot1* and *pox1* were selected as integral enzymes required for beta-oxidation. Genes *pex5* and *pex7* are peroxisome transport proteins responsible for import of peroxisome-specific proteins. The gene *inp2* was selected for its role in peroxisomal inheritance and the two genes *slt2* and *atg36* were selected for their role in pexophagy. The peroxisomal *pha* enzymes were expressed in all thirteen knockout mutants and the wild-type yeast for five days in YN media at varied concentrations of oleic acid (*Fig. 4*). Beta oxidation gene knockouts  $\Delta pot1$ , and  $\Delta pox1$ , as well as peroxisomal transport protein knockouts  $\Delta pex5$  and  $\Delta pex7$  exhibited dramatic decreases in PHB production. Knockout strain  $\Delta aat2$  showed relatively little change relative to the wild type while  $\Delta adr1$  exhibited decreased PHB production (*Fig. 4a*). None of the three fatty acid synthesis repressor knockouts ( $\Delta rpd3$ ,  $\Delta sin3$  and  $\Delta opi1$ ) had a significant effect on PHB levels at 0.2% or 0% oleate concentrations but  $\Delta sin3$  and  $\Delta opi1$  exhibited decreased production of PHB at 0.5% oleate relative to the wild type.

## Discussion

The compartmentalized peroxisomal biosensor for acetyl-CoA was constructed and demonstrated (*Fig. 2*). The cytosolic variant of the PHB pathway was not significantly affected by oleate concentrations because acetyl-CoA in the cytosol was mostly derived from glucose. The peroxisomal variant of the PHB pathway, however, demonstrated a strong correlation between oleic acid content and PHB production, because acetyl-CoA in the peroxisome is mostly derived from beta-oxidation of fatty acids such as oleic acid (Chen, Siewers & Nielsen, 2012). There was also no detectable PHB produced from the peroxisomal pathway in *Fig. 2* when oleic acid was absent, suggesting minimal leakage of cytosolic acetyl-CoA into the peroxisome. Therefore, it is appropriate to use PHB production from the compartmentalized biosensor to indicate the peroxisomal acetyl-CoA level.

Even with similar levels of glucose and oleic acid, the peroxisomal variant strain, phbP did not produce as much PHB as the cytosolic variant, phbC, within 48 hours (*Fig. 2*), so it was hypothesized that two days of incubation was not long enough for the yeast cells to fully switch from glucose utilization to fatty acid utilization (Gurvitz & Rottensteiner, 2006). Growth and production curves, shown in *Fig. 3* demonstrate that PHB production in the phbP strain started only after 24 hours, which is the same amount of time required to reach stationary phase. This suggests that the yeast cells used glucose for cellular growth until it was depleted, then switched to beta-oxidation of oleic acid. However, the strain phbP was never able to generate as much PHB as the cytosolic control, phbC, even when given similar quantities of oleic acid and glucose and ample time to utilize oleic acid.

The compartmentalized biosensor was then applied to screening several single-gene knockouts for altered acetyl-CoA availability in the peroxisome. As expected,  $\Delta pot1$ ,  $\Delta pox1$ ,  $\Delta pex5$  and  $\Delta pex7$  all exhibited dramatic decreases in peroxisomal PHB production as those genes are necessary for beta oxidation. Similarly,  $\Delta adr1$  reduced PHB production because of its role in activating fatty acid utilization. It is puzzling, however, that the  $\Delta pex5$  strain did not exhibit high levels of cytosolic PHB production. Since pex5 is a transport protein needed for peroxisomal localization of PTS1-tagged proteins, it was expected that the biosensor enzymes would accumulate in the cytosol as has been observed for PTS1 tagged yellow fluorescent protein (DeLoache, Russ & Dueber, 2016). However, the *pex5* knockouts in this study did not perform similarly to the strains using enzymes without PTS1 tags. The reason for this is still unclear.

Other knockouts were predicted to increase peroxisomal acetyl-CoA. Fatty acids generated by the cell could be used to supplement the exogenous source of oleic acid for beta-oxidation. As repressors of fatty acid synthesis,  $\Delta rpd3$ ,  $\Delta sin3$  and  $\Delta opi1$  had potential to increase PHB levels by providing additional fatty acids from the cytosol to be digested in the peroxisome. However, no dramatic increase in PHB was observed for these knockouts.

Unlike the two-day cultures used for *Fig. 2*, the five-day cultures in the knockout experiments showed low levels of PHB production even in the absence of oleate. This could be caused by acetate being produced and converted to acetyl-CoA in the peroxisome by the pyruvate dehydrogenase bypass after the glucose had been depleted (Nielsen, 2014). PHB might also be produced by low, native availability of acetoacetyl-CoA and 3-hydroxybutyric-CoA intermediates. In a study by Leaf et al., yeast cells with only the exogenous phaC enzyme were able to produce PHB, albeit at only 1 mg/g DCW (Leaf et al., 1996). Intermediates produced in this manner would still be positively correlated to acetyl-CoA availability in the peroxisome, and thus, do not interfere with the intended function of the biosensor.

Overall, this study illustrates only one specific application of a compartmentalized biosensor, but the strategy could be applied to other metabolites in other compartments. For example, the concentrations of acetyl-CoA in the mitochondria have been estimated to be 20-30 times higher than in the cytosol(Weinert et al., 2017) and a recent study involved re-localizing heterologous enzymes for the production of valencene to the mitochondria of *S. cerevisiae* via targeting signal peptides resulting in increased production compared to cytosolic expression of those same enzymes(Farhi et al., 2011). Further optimization of this localized pathway could benefit from a biosensor similar to ours to detect the critical precursor, farnesyl diphosphate (FDP). FDP can be detected using a fluorescent enzymatic assay(Dozier & Distefano, 2012) and compartmentalization of this assay could be accomplished by introducing N-terminal mitochondrial localization signal (MLS) tags such as from subunit IV of the yeast cytochrome C oxidase (CoxIV) to the enzymes of the fluorescent assay(Avalos, Fink & Stephanopoulos, 2013).

## Conclusions

We developed an assay that used three compartmentalized enzymes to convert peroxisomal acetyl-CoA to a reporter compound, PHB. By quantifying PHB levels, we successfully applied this compartmentalized biosensor to screen a library of yeast mutants and identified knockouts with drastically impaired PHB synthesis, which suggest the possibility that overexpression of some those genes might result in increased PHB production. Metabolic engineering of compartmentalized pathways requires measurement tools for pathway design and evaluation. Traditional methods for measuring metabolite concentrations are generally limited to cytosolic or whole-cell sources of the metabolite. In contrast, as shown in this study, compartmentalized biosensors could be a valuable addition to current synthetic toolkits on analyzing intracellular metabolites. We anticipate that the compartmentalized biosensors can be used to better understand the compartmentalized metabolism in various organelles and facilitate “design-build-test” cycle of compartmentalized metabolic engineering.

# Figure 1

Figure 1 . Mechanism of the localized biosensor.

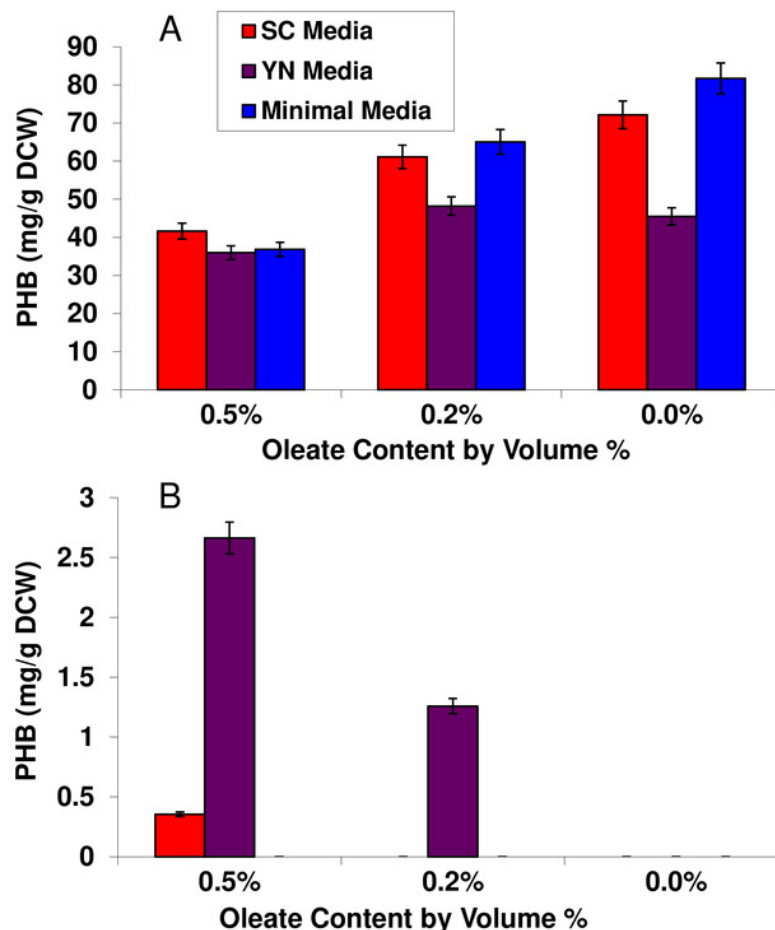

The three enzymes phaA, phaB and phaC were expressed from a plasmid and contained enhanced PTS1 localization tags. The tags were rapidly recognized by the pex5 protein that shuttled the enzymes into the peroxisome. There, the enzymes converted peroxisomal acetyl-CoA into PHB which was subsequently extracted and detected by HPLC.

# Figure 2

Figure 2. Oleic acid dependency of peroxisomal PHB.

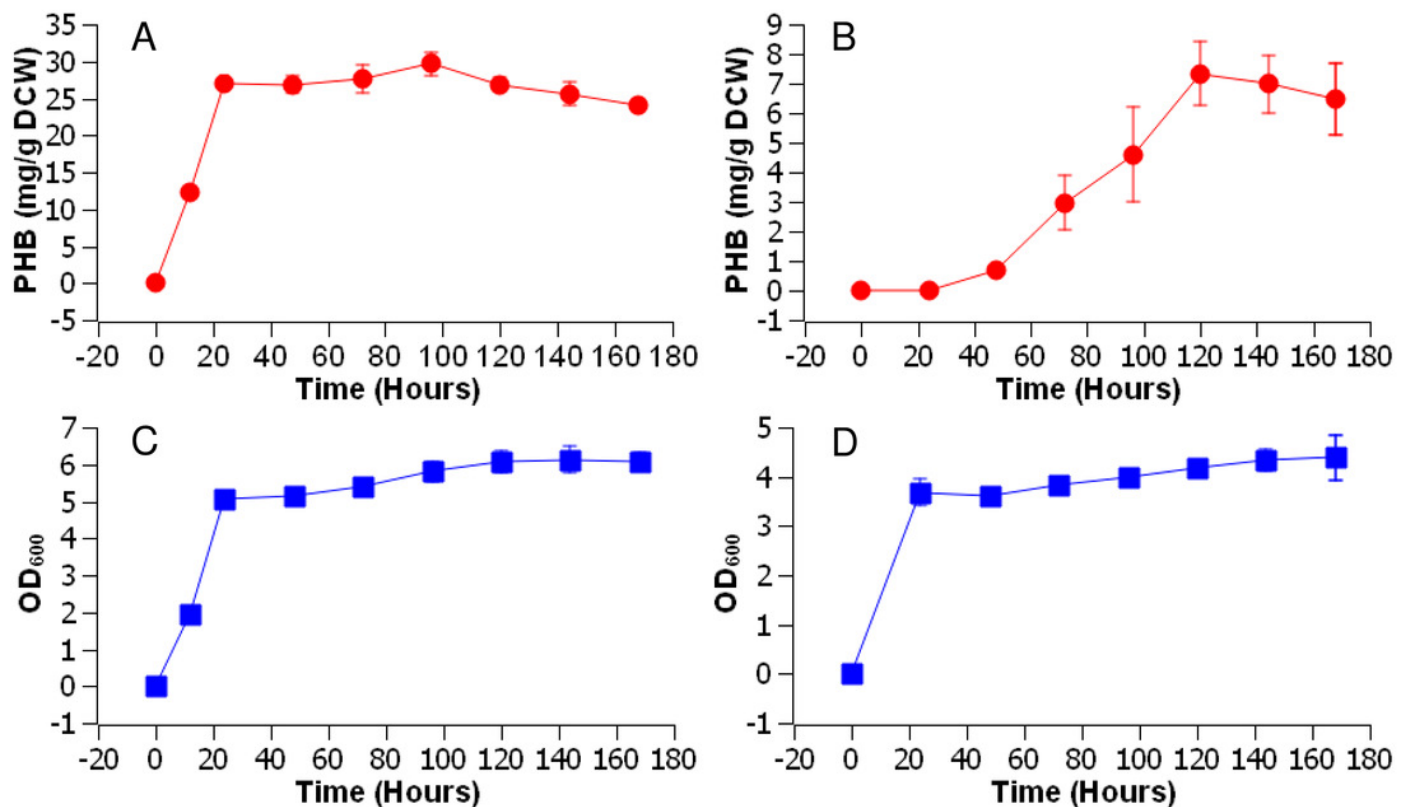

Yeast strains with PHB producing enzymes were incubated for 48 hours in several media and with varied concentrations of oleic acid. A) Yeast strain *phbC* containing the three *pha* enzymes without enzyme localization. B) Yeast strain *phbP* with the three *pha* enzymes with localization tags. ND: Not Detectable. Error bars show estimated instrument error.

# Figure 3

Figure 3. PHB production and growth curves for cytosolic and peroxisomal strains.

Both strains were cultured for five days in YN media with 0.5% oleic acid. A) PHB content vs. time for the cytosolic strain phbC. B) PHB content vs. time for phbP. C) Growth curve for the phbC. D) Growth curve for phbP. Error bars show standard deviation among triplicate cultures.

# Figure 4

Figure 4. Screening of mutants using the peroxisomal acetyl-CoA assay.

Yeast knockout strains and the wild type (WT) were incubated for five days in YN media with various oleic acid concentrations. A) PHB concentration. B) Cell density (in OD<sub>600</sub>) of the mutant screening cultures. ND: Not Detectable. Error bars show estimated instrument error.
