Many subclades within the large North American freshwater fish genus *Etheostoma* (Percidae) show brilliant male nuptial coloration during the spring spawning season. Traditionally, perceived differences in color were often used to diagnose closely related species. More recently, perceived differences in male nuptial color have prompted further investigation of potential biodiversity using genetic tools. However, cryptic diversity among *Etheostoma* darters renders male nuptial color as unreliable for detecting and describing diversity, which is foundational for research and conservation efforts of this group of stream fishes. *Etheostoma raneyi* (Yazoo Darter) is an imperiled, range-limited fish endemic to north-central Mississippi. Existing genetic evidence indicates cryptic diversity between disjunctly distributed *E. raneyi* from the Little Tallahatchie and Yocona river watersheds despite no obvious differences in male color between the two drainages. Analysis of morphological truss and geometric measurements and meristic and male color characters yielded quantitative differences in *E. raneyi* from the two drainages consistent with genetic evidence. Morphological divergence is best explained by differences in stream gradients between the two drainages. *Etheostoma faulkneri*, the Yoknapatawpha Darter, is described as a species under the unified species concept. The discovery of cryptic diversity within *E. raneyi* would likely not have occurred without genetic tools. Cryptic diversity among *Etheostoma* darters and other stream fishes is common, but an overreliance on traditional methods of species delimitation (i.e., identification of a readily observable physical character to diagnose a species) impedes a full accounting of the diversity in freshwater fishes in the southeastern United States.

## 20 Introduction

21 *Etheostoma raneyi* Suttkus and Bart (Yazoo Darter) is most closely related to other snubnose  
22 darters in western Tennessee and Kentucky and Alabama (unranked clade name *Adonia*, *sensu*  
23 Near et al., 2011) (Kozal et al., 2017). The species is distributed across small tributaries of the  
24 Little Tallahatchie (L.T.R.) and Yocona rivers (Y.R.) of north-central Mississippi in the upper  
25 Yazoo River basin (Figure 1). *Etheostoma raneyi* avoid the bottomland streams of the  
26 Mississippi Alluvial Plain and is limited to relatively higher-gradient, perennial streams draining  
27 sandy geologic formations of the Upper Gulf Coastal Plain (Stephenson et al., 1928; Randolph &  
28 Kennedy, 1974; Thompson & Muncy, 1986; Suttkus et al., 1994; Thompson, 2011; Sterling et  
29 al., 2013).

30 A phylogenetic study of Coastal Plain snubnose darters in western Tennessee and Kentucky,  
31 and northern Mississippi, including *E. raneyi*, uncovered substantial genetic structure within and  
32 among species that was attributed to watershed configurations and the location of stream  
33 confluences between large drainages within the unfavorable lowland habitat of the Lower Gulf  
34 Coastal Plain and Mississippi Alluvial Plain (Powers & Warren, 2009; Keck & Etnier, 2005)  
35 (Figure 1). *Etheostoma raneyi* from the L.T.R. and Y.R. drainages were recovered as  
36 reciprocally monophyletic lineages, indicating that individuals from each drainage were  
37 evolutionarily divergent and distinct (Powers & Warren, 2009). A more recent phylogenetic  
38 analysis using two genes and greater number of samples from across the range of the species also  
39 indicated that *E. raneyi* in the two drainages were independently evolving metapopulations  
40 (Sterling et al., 2020). Estimated time since divergence (0.4-0.8 my) was similar to estimates for  
41 snubnose darters in western Tennessee and Kentucky (Kozal et al., 2017).

42 The original description of *E. raneyi* did not indicate any geographic variation in appearance,  
43 male nuptial color, morphology, or meristics except for modal lateral-line scale counts between  
44 the L.T.R. and Y.R. (Suttkus et al., 1994). However, an examination of standard lengths (SL)  
45 between drainages showed that males and females from the Y.R. were longer compared with  
46 males and females from the L.T.R. (Sterling et al., 2013). Because the available evidence  
47 suggested possible differences in meristic and morphological characters and because the genetic  
48 evidence indicated that *E. raneyi* in the Y.R. were distinct, we investigated possible differences  
49 in male nuptial color, meristic characters, and morphology. The description of the new species  
50 presented here is based on published data and our new analyses.

51

## 52 **Materials and Methods**

53 This study was conducted with the approval of the University of Mississippi IACUC Committee  
54 (protocol 09-027), using annual collection permits issued to us from the Mississippi Museum of  
55 Natural Science (Mississippi Department of Wildlife, Fisheries, and Parks) for the years 2009-  
56 2014: 0604091, 0513101, 0624112, 0622122, 0602132, 0610142.

57

### 58 *Male nuptial color*

59 We examined male nuptial color by taking photographs of mature, live fish in the field. Males  
60 were captured by seine and deposited into a water-filled, opaque black bucket with a lid and  
61 supplemental oxygen (a bubbler) to prevent stress and subsequent loss of color. We used a small,  
62 clear Plexiglas photarium with a white foam squeeze plate to obtain images of a lateral view of  
63 the entire individual. We made all photographs using an Olympus Stylus TG-3 camera. Though  
64 one of us (K.S.) edited images for brightness and contrast, no alterations were made to hue or

65 saturation. We made collections from February to April 2017 and March to April 2018 when  
66 males are at the peak of nuptial color (Table 1). We made a total of seven collections from six  
67 streams in the L.T.R. drainage (n = 51) and eight collections from five streams in the Y.R.  
68 drainage (n = 36). We used resulting images to characterize colors and pigment patterns.

69 To assess possible color and pigment pattern differences between drainages following  
70 preliminary comparisons by one of us (K.S.), we asked three colleagues to score images of  
71 darters (see Supplement for data) for three characters: 1) the presence and density of black  
72 pigment in the pelvic and median fins, breast, branchiostegal membranes, chin, opercle, and  
73 cheek, which were scored as 1 = little pigment, 2 = moderate pigment, 3 = heavy pigment; 2) the  
74 presence and density of blue pigment in the same areas as for black pigment, which were scored  
75 identically; 3) presence of a clear window in the anal fin scored as 1 = window is small to non-  
76 existent and covers  $\leq 3$  membranes, blue pigment mostly extends to the belly, 2 = window is  
77 large and covers  $\geq 3$  membranes, blue pigment mostly does not extend to the belly.

78 Images were presented in random order and with no information on the location from which  
79 they were sampled. We compiled the scores across all three surveys, and we calculated means  
80 and 95% confidence intervals of scores for each drainage. Because this artificially reduces  
81 variance, we also present the results from each individual survey in the Supplement. Lastly, we  
82 also calculated the proportion of males having orange pigment in the anal fin from each drainage.

83

#### 84 *Meristic, truss morphometric, and geometric morphometric analyses*

85 We counted meristic characters following the methods of Hubbs & Lagler (2004) except we  
86 counted transverse scales from the origin of the anal fin diagonally toward the base of the  
87 spinous dorsal fin (Page, 1983). For comparison, we compiled meristic data for closely related

88 Adonia snubnose darters (Near et al., 2011) from several sources in the literature (Bailey &  
89 Etnier, 1988; Powers & Mayden, 2003; Kozal et al., 2017). Counting methods were clearly  
90 different for one source (Kozal et al., 2017) compared with our methods and other data sources  
91 as evidenced by differences in modal counts that were consistently either one count higher or  
92 lower. In one instance (second dorsal fin rays) this difference in method was cited in the text. We  
93 adjusted counts for consistency with other sources of data, except for caudal peduncle scales  
94 because of small sample size and no clear modal count.

95 We made morphometric truss measurements following Hubbs & Lagler (2004) and  
96 Humphries et al. (1981) (Figure 2). We measured distances between 28 pairs of points (digital  
97 calipers, nearest 0.1 mm) and converted them to thousandths of SL to remove the effects of  
98 differences in length (Grabowski et al., 2018). We checked distributions of each variable in PC-  
99 Ord ver. 6.21 (McCune & Mefford, 2011) and, as expected, variables showed little skew and  
100 roughly normal distributions. We then estimated means and 95% confidence intervals for each  
101 variable using resampling with replacement and 10,000 samples (Statistics.com LLC, 2009).  
102 Specimens were primarily from our own collections now deposited with the National Museum of  
103 Natural History (Washington, D.C.) (USNM) or the Mississippi Museum of Natural Sciences  
104 (Jackson, MS) (MMNS). We obtained additional specimens from Tulane University Biodiversity  
105 Research Institute (Belle Chasse, LA) (TU). *Etheostoma raneyi* mature at about 28-30 mm SL  
106 (Suttkus et al., 1994), so we only used specimens >30 mm SL.

107 We used geometric morphometric analyses to test for and describe differences in shape  
108 between *E. raneyi* in the L.T.R. and Y.R. We chose to use a morphometric approach rather than  
109 more traditional multivariate analysis of linear truss measurements because the morphometric  
110 approach describes changes in shape among all landmark points simultaneously and produces

111 clear graphics of shape changes among groups (Bookstein, 1991; Parsons et al., 2003;  
112 Klingenberg, 2013).

113 Morphometric analysis requires images of each specimen, and a set of uniform landmark  
114 points plotted on each image before analysis. We photographed the lateral view of the left side of  
115 the entire fish using an Olympus Stylus TG-3 camera mounted on a vertical camera stand. A  
116 glass plate was placed on top of the fish to reduce curvature. Each image included a specimen ID  
117 label and a scale (mm). We imported images into tpsUtil (ver. 1.74, Rohlf, 2017a) and tpsDig  
118 (ver. 2.30, Rohlf, 2017b) software. We plotted, scaled, and digitized landmarks to produce  
119 Cartesian grid coordinates for each individual using 20 homologous landmarks (Figure 3).  
120 Because preserved specimens are often vertically curved, we used tpsUtil (ver. 1.74, Rohlf,  
121 2017a) to straighten landmark coordinates along the midline of the body.

122 We imported output from the tps software into MorphoJ software for all subsequent analyses  
123 (Klingenberg; 2011, 2018). We compared shapes for males and females between drainages and  
124 compared shapes between sexes within each drainage (L.T.R. and Y.R.) (Table 2).

125 We used the outlier function in MorphoJ to remove individuals that may have biased the  
126 results and performed a least-squares full procrustes superimposition to remove bias resulting  
127 from differences in position and orientation among individuals (Mitteroecker & Gunz, 2009;  
128 Klingenberg, 2011; Klingenberg & Marugán-Lobón, 2013). Pooled within-group multivariate  
129 regression of shape data (Procrustes coordinates) against  $\log_{10}$  centroid size removed possible  
130 bias resulting from ontogenetic allometry; we used the resulting residual shape variation for all  
131 subsequent analyses in MorphoJ (Loy et al., 1998; Klingenberg, 2011). We used discriminant  
132 analysis (DA) to test for differences in shape for all comparisons. We estimated mean Procrustes  
133 distance (PD) and Mahalanobis distance (M) for each comparison and ran a permutation test

134 (10,000 permutations) to estimate p-values. We used cross-validated classification tables to  
135 assess the reliability of the DA results and produced shape change graphics from DA output for  
136 all comparisons.

137 Preliminary results indicated shape changes between drainages that suggested possible  
138 differences in stream gradients. Therefore, we calculated watershed area (km<sup>2</sup>) and stream  
139 gradient (relief/length of stream) for all streams with Yazoo Darters in each drainage using  
140 DeLorme Topo USA ver. 7.1.0 (2007) and estimated means. We used resampling with  
141 replacement to calculate 95% confidence intervals of mean values using Resampling Stats ver.  
142 4.0 (Statistics.com LLC, 2009).

143 We evaluated all data and results from analyses under the unified species concept (de  
144 Queiroz, 2007). Data used for morphological analyses (MorphoJ) are available from the open  
145 access MorphoBank (O'Leary & Kaufman 2012) data repository at:  
146 [https://morphobank.org/index.php/MyProjects/List/select/project\\_id/3712](https://morphobank.org/index.php/MyProjects/List/select/project_id/3712). Fishes examined for  
147 the truss morphological measurements were borrowed from the Tulane University Biodiversity  
148 Research Institute (Belle Chasse, LA) (TU) or were from our own collections now archived at  
149 the National Museum of Natural History (Washington, D.C.) (USNM) and the Mississippi  
150 Museum of Natural Sciences (Jackson, MS) (MMNS). Images used for male nuptial color  
151 comparisons are available in the Supplement.

152 The electronic version of this article in Portable Document Format (PDF) will represent a  
153 published work according to the International Commission on Zoological Nomenclature (ICZN),  
154 and hence the new name contained in the electronic version are effectively published under that  
155 Code from the electronic edition alone. This published work and the nomenclatural acts it  
156 contains have been registered in ZooBank, the online registration system for the ICZN. The

157 ZooBank LSIDs (Life Science Identifiers) can be resolved and the associated information viewed  
158 through any standard web browser by appending the LSID to the prefix <http://zoobank.org/>. The  
159 LSID for this publication is: urn:lsid:zoobank.org:pub:6C5BEC69-22A1-4008-84D3-

161 digital repositories: PeerJ, PubMed Central and CLOCKSS.

162

## 163 **Results**

### 164 *Male nuptial color*

165 Preliminary examination of photographed male darters indicated that possible color or pigment  
166 pattern differences were subtle and appeared limited to: 1) generally more extensive and denser  
167 black pigment in the pectoral and median fins and the breast, cheek, opercle, and ventral portion  
168 of the head region for individuals sampled in the L.T.R.; 2) generally more extensive and denser  
169 blue pigment in the same areas for individuals from the Y.R.; 3) complete absence or a small  
170 clear window in the anal fin for fish from the Y.R. compared with windows always being present  
171 and larger in the L.T.R.; 4) orange pigment occasionally present in the anal fin of fish from the  
172 L.T.R. and never present in fish from the Y.R. (Figure 4).

173 Independent scoring of these features revealed that these average differences are consistent  
174 between the drainages (Figure 5). Blue pigment was more dense and extensive in the Y.R. males,  
175 but black pigment was generally more dense and extensive in the L.T.R. males. Clear windows  
176 in the anal fin were generally smaller or absent in the Y.R. individuals (Figure 4). Orange  
177 pigment in the anal fin was not found in fish from the Y.R., but was present in 17.7% of males  
178 from four of six streams sampled in the L.T.R.

179

180 *Meristics and truss measurements*

181 Count data for lateral-line scales show a bimodal distribution that differ by two scales between  
182 individuals from the Y.R. and L.T.R. (Table 3), which is consistent with the counts of Suttkus et  
183 al. (1994). There are no other modal differences between the Y.R. and the L.T.R. drainages  
184 (Tables 4-9).

185 Mean proportional values for truss measurements indicate that individuals from the Y.R. are  
186 more robust with shorter heads and snouts relative to individuals from the L.T.R. Dorsal fins are  
187 also longer in the Y.R., but gape width and the position of the mouth relative to the tip of the  
188 snout shows no difference. Females in the L.T.R. have a wider inter-orbital width, but females in  
189 the Y.R. had a wider body at the pectoral fin insertion. Overall, 13 of 29 characters did not have  
190 overlapping 95% CIs for at least one sex between drainages. Mean SL for both males and  
191 females in the Y.R. is longer than for males and females in the L.T.R. (Table 10).

192

193 *Geometric morphological analyses*

194 The outlier function in MorphoJ identified two females and two males in the L.T.R. as  
195 potentially biasing results and these were removed. No individuals from the Y.R. were identified  
196 as possible outliers.

197 There were significant differences in shape between females in the L.T.R. ( $n = 51$ ) and Y.R.  
198 ( $n = 60$ ) drainages (DA, PD = 0.014,  $p < 0.0001$ ; M = 3.59,  $p < 0.0001$ ). Classification of  
199 specimens to groups shows that 12% of individuals from the L.T.R. were incorrectly assigned to  
200 the Y.R. drainage and 17% of individuals from the Y.R. were incorrectly assigned to the L.T.R.  
201 drainage. Yocona River females had shorter snouts and heads (points 4 and 16), greater body  
202 depth, longer second dorsal fin (point 7), longer anal fin associated with an anterior shift in the

203 insertion (point 12), and the posterior edge of the hypural plate shows a shift anteriorly (Figure  
204 6).

205 There were significant differences in shape between males in the L.T.R. ( $n = 50$ ) and Y.R. ( $n$   
206  $= 49$ ) (DA, PD = 0.009,  $p < 0.0001$ ;  $M = 2.78$ ,  $p < 0.0001$ ). Classification of specimens to groups  
207 shows that 32% of individuals from the L.T.R. were incorrectly assigned to the Y.R. and 29% of  
208 individuals from the Y.R. were incorrectly assigned to the L.T.R. Shape changes between  
209 drainages show that Y.R. males had shorter snouts and heads (points 4 and 16), greater body  
210 depth, and longer second dorsal fins (point 7) (Figure 6).

211 There were significant differences in shape between males ( $n = 50$ ) and females ( $n = 51$ )  
212 within the L.T.R. drainage (DA, PD = 0.015,  $p < 0.0001$ ;  $M = 3.05$ ,  $p < 0.0001$ ). Classification of  
213 specimens to groups shows that 20% of females were incorrectly classified as males and 25% of  
214 males were incorrectly classified as females. Relative shape changes between males and females  
215 show that females are thinner with longer caudal peduncles, the insertion of the pectoral and  
216 pelvic fins shifted anteriorly, and the insertion of the anal fin shifted posteriorly relative to males  
217 (Figure 7).

218 There were also significant differences in shape between males ( $n = 49$ ) and females ( $n = 60$ )  
219 within the Y.R. drainage (DA, PD = 0.013,  $p < 0.0001$ ;  $M = 4.63$ ,  $p < 0.0001$ ). Cross-validated  
220 classification of specimens to groups shows that 3% of females were incorrectly classified as  
221 males and 5% of males were incorrectly classified as females. Relative shape changes between  
222 males and females show that females are thinner, the snout is shorter, the anal and second dorsal  
223 fins are shorter, the insertion of the pectoral and pelvic fins shifts anteriorly, and the insertion of  
224 the anal fin shifts posteriorly relative to males (Figure 7).

225 Comparison of watershed area and stream gradients between drainages show that *E. raneyi* in  
226 the L.T.R. mostly occur in larger streams with lower gradients compared with the Y.R. (Figure 8,  
227 Table S1). Mean watershed area is >twice as large in the L.T.R., and mean gradient is about 45%  
228 greater in the Y.R. drainage. Confidence intervals do not overlap for area or gradient.

303

#### 304 *Diagnosis and description*

305 *Etheostoma faulkneri* is one of at least 27 species, undescribed forms, or Evolutionary  
306 Significant Units of snubnose darters in the unranked clade Adonia (*sensu* Near et al., 2011; see  
307 Blanco, 2001; Brogdon et al., 2003; Boschung & Mayden, 2004; Gabel, 2007; Kozal et al., 2017)  
308 (Table S2) and is indicated as the sister species of *E. raneyi* (Sterling et al., 2020). Consistent  
309 with other Adonia snubnose darters, *E. faulkneri* lack a frenum and usually have several long,  
310 thin teeth on the vomer (Suttkus et al., 1994; Kozal et al., 2017). Modal lateral line scale counts  
311 differ between *E. faulkneri* (45) and *E. raneyi* (47). *Etheostoma faulkneri* males and females  
312 have shorter snouts and heads and more robust bodies relative to *E. raneyi* and are longer.  
313 Compared with *E. raneyi*, male *E. faulkneri* usually have a smaller or no clear window in the  
314 blue anal fin and more extensive blue pigment on the anal fin, second dorsal fin, procurrent rays  
315 of the caudal fin, the cheek, opercle, and tip of the snout during the spawning season.  
316 *Etheostoma faulkneri* also lack orange pigment in the anal fin which is present in a small  
317 proportion (17.7%) of male *E. raneyi*, and the black pigment on the opercle, cheek, chin,

318 branchiostegal rays, pelvic fins, second dorsal fin, and caudal fin is generally less dense and less  
319 extensive for *E. faulkneri* than for *E. raneyi*. This results in spawning male *E. faulkneri* usually  
320 appearing brighter blue overall than *E. raneyi*, which appear duskier overall (Figure 4).

321 *Etheostoma faulkneri* can be distinguished from *E. raneyi* by fixed allele differences at 12  
322 loci on the mitochondrial *cytb* gene and one difference and two deletions on the nuclear *S7* gene  
323 (Sterling et al., 2020). Maximum length for *E. faulkneri* is a 64 mm SL male sampled from  
324 Morris Creek. For females, three 49 mm SL individuals were each sampled from Yellow Leaf,  
325 Johnson, and Morris creeks. Maximum SL for *E. raneyi* is 57 mm for males and 50 mm for  
326 females (unpubl. data).

327 The lateral line is complete with 41-51 scales (mode = 45) (Table 3). The last scale is  
328 sometimes unpored. Transverse scales range from 11-15 (Table 4), and scales around the caudal  
329 peduncle range from 16-19 (Table 5). Dorsal fin spines range from 9-11 (mode = 10), second  
330 dorsal fin rays range from 9-11 (mode = 11) (Tables 6-7), anal fin rays range from 6-8 (mode =  
331 7), and pectoral fin rays range from 13-15 (mode = 14) (Tables 8-9). The belly, nape, cheek, and  
332 opercle are scaled, and the breast is usually naked but frequently has several scales, especially  
333 for larger individuals. The prepectoral area is often scaled, but for some individuals scales are  
334 limited in extent.

335 The spinous dorsal fin of male *E. faulkneri* have a bright turquoise margin, an incomplete  
336 medial band of bright red in the posterior 3-5 interradiial membranes that fades anteriorly into a  
337 metallic gold color best seen against a black background but appears as beige patches of pigment  
338 against light backgrounds (described as pale cream in Suttkus et al., 1994). A band of black that  
339 is usually incomplete is basal to the red and gold band and is present in the anterior 1-6 fin  
340 membranes. During the spawning season, this black band is often suffused or overlain with

341 turquoise pigment. The soft dorsal fin has a diffuse posterior patch of turquoise on the fin  
342 margin; the turquoise pigment becomes limited to the fin rays anteriorly and does not compose a  
343 band of color (there is no marginal band of turquoise in the soft dorsal fin as described in Suttkus  
344 et al., 1994 for either *E. raneyi* or *E. faulkneri*). A bright orange medial band of color in the  
345 interradial membranes extends from the posterior edge of the soft dorsal fin and fades and  
346 becomes thinner anteriorly through 5-8 membranes. A basal patch of black pigment often occurs  
347 where the fin meets a dorsal saddle. Black pigment is frequently present in the interradial  
348 membranes of the fin but is usually less dense and less extensive in area compared with *E.*  
349 *raneyi*, though in some individuals the black pigment is well developed.

350 The anal and pelvic fins are bright turquoise in nuptial males. A small, thin, clear to creamy  
351 medial window in the anal fin is often present in the posterior 2-3 interradial membranes.  
352 Turquoise pigment is well developed from the margin of the anal fin to the belly. In contrast, *E.*  
353 *raneyi* usually have larger windows that cover 3-4 membranes and are wider. In some  
354 individuals, black pigment is present in the membranes of the pelvic fins, which is usually denser  
355 and more extensive in *E. raneyi*. The pectoral fins are mostly devoid of pigment, but the rays  
356 have intense orange pigment proximal to the fin insertion. The caudal fin is mostly clear, but the  
357 procurrent rays of nuptial males are bright turquoise blue, and the primary rays may have some  
358 green, blue, or black pigment.

359 The background color of adult males is a warm cream color dorsally that becomes paler  
360 ventrally. Large males have intense dark orange pigment from the mid-ventral area up to the  
361 mid-lateral stripe that fades to a lighter, bright orange anteriorly. In some males, the orange is  
362 also present in the prepectoral area. In smaller males, the orange is reduced to a band of pigment  
363 along the side of the belly that does not extend to the mid-lateral stripe or to the anal fin. Two

364 basicaudal spots of orange are almost always present. The mid-lateral stripe consists of a series  
365 of blotches bisected by a depigmented lateral line that becomes indistinct posteriorly. Blotches  
366 alternate between a dark brown to black color and a dark red color. The dark red blotches are  
367 usually elongate rectangles. The dark brown or black blotches are often the ventral portion of a  
368 y-shaped pattern that extends to the dorsal fins and is connected by the dorsal saddles, of which  
369 there are eight (see Figure 4). However, these blotches are irregularly shaped and patterns are  
370 often irregular, especially anteriorly. The dark brown and black pigment becomes an irregular  
371 series of spots and blotches on the head. A dark to dusky suborbital bar extending below the eye  
372 is usually present as is a dark pre-orbital stripe. The top of the head is the same dark brown as the  
373 dorsal saddles. In nuptial males, there may be green to turquoise tint to the top of the head and  
374 anterior saddles as well as the tip of the snout. A clear, bright turquoise color is present on the  
375 pre-opercle, opercle, cheek, chin, branchiostegal rays, and breast. In some individuals, black  
376 spots of pigment are present in these areas which cause the bright turquoise to appear dusky, an  
377 effect more often seen in *E. raneyi*.

378 Females are more cryptically colored although the pigment patterns of the mid-lateral stripe  
379 and dorsal surface of the body are highly similar to the male. The background color is a neutral  
380 tan dorsally and becomes an unsullied bright white ventrally. The mid-lateral stripe is an  
381 alternating series of dark maroon to warm brown and dark brown to black blotches bisected by  
382 an unpigmented lateral line that becomes more indistinct posteriorly. The maroon or warm  
383 brown blotches are elongate rectangles and the dark brown to black blotches are usually irregular  
384 in size and shape, sometimes connected to the dorsal saddles. Blotches become more irregular  
385 anteriorly and are small on the head and opercle. A dark to dusky pre-orbital stripe and  
386 suborbital bar usually are present. The belly is usually devoid of pigment, though larger females

387 may have some small spots of orange pigment. Two orange basicaudal spots are almost always  
388 present. In nuptial females, a light wash of turquoise may occur on the breast, tip of the snout,  
389 and top of the head. Fins are all mostly devoid of bright pigment with clear membranes and a  
390 series of elongate dark brown to black areas of pigment on the straw-colored dorsal and caudal  
391 fin rays. Occasionally, the red median band in the spinous dorsal fin of males is present in  
392 females though the color is much less intense and often appears as an indistinct series of spots in  
393 the most posterior 1-3 membranes. The pelvic, pectoral, and anal fins are usually clear though an  
394 indistinct wash of turquoise may be present in the anal fin.

395

396 *Distribution:* *Etheostoma faulkneri* is endemic to perennial headwater tributaries of the Y.R.  
397 drainage. To the east, distribution appears limited by the increased presence of intermittent  
398 streams in terrain with less relief and more extensive agricultural land (Figure 1). Otoucalofa  
399 Creek, a large tributary to the Y.R., may have the largest connected population of *E. faulkneri*  
400 (Sterling et al.; 2012, 2013). The species is known from 33 sites in 20 streams; 11 streams are in  
401 the Otoucalofa Creek system (Table S3), and future sampling will likely yield *E. faulkneri* in  
402 several additional streams that appear to have suitable habitat. However, repeated sampling  
403 indicates that *E. faulkneri* are uncommon in most streams of occurrence and may even be  
404 extirpated from Smith Creek in Calhoun County (unpubl. data). The earliest known collection  
405 was by R.D. Suttkus on May 24, 1952 when 11 individuals were taken in Pumpkin Creek at State  
406 Highway 6, Lafayette Co., Mississippi (Tulane University: TU3116).

407

408 *Habitat and biology*

409 The biology and habitat use of *E. faulkneri* is apparently similar to that of *E. raneyi* (Knight &  
410 Cooper, 1987; Suttkus et al., 1994; Sterling & Warren, 2017). A life history study of *E. faulkneri*  
411 was conducted at Morris Creek (Johnston & Haag, 1996), results of which are consistent with the  
412 literature for other clade Adonia snubnose darters (Carney & Burr, 1989; Khudamrongsawat &  
413 Kuhajda, 2007; Barton & Powers, 2010). In our experience in the field, *E. faulkneri* are most  
414 commonly sampled from less-disturbed small streams with strong perennial flow and plentiful  
415 instream cover (wood or hard clay riffles). In streams lacking cover because of channelization,  
416 incisement, and sedimentation, the species is often collected from the rubble, wood pilings, and  
417 human refuse associated with bridge crossings and is sparse elsewhere. The first known  
418 description of habitat use by *E. faulkneri* (specific to the Otoucalofa Creek watershed) indicates  
419 that the species are usually found in densely canopied first-order streams that have not been  
420 clear-cut, and are associated with hard-clay riffles (Knight & Cooper, 1987).

421

#### 422 *Conservation management*

423 *Etheostoma faulkneri* is restricted to one headwater drainage in the upper Yazoo River basin with  
424 a total area of only about 1500 km<sup>2</sup> (relative to about 3200 km<sup>2</sup> for *E. raneyi*) and is distributed  
425 almost entirely on private lands (Sterling et al., 2013). As described earlier, the species has low  
426 genetic diversity and is nowhere abundant outside of small stream reaches associated with some  
427 road crossings. The upper Yazoo River basin is highly modified, in common with neighboring  
428 drainages to the north in western Tennessee with snubnose darters, and stream alterations have  
429 obliterated most suitable habitat (Shields et al., 1995; Warren et al., 2002; Keck & Etnier, 2005;  
430 Fore et al., 2019). Urban development in the Y.R. drainage is increasing rapidly in association  
431 with the explosive growth of the city of Oxford and, to a lesser extent, Water Valley, MS. As a

432 result, *E. faulkneri* faces increasing habitat degradation through time across most of its range.  
433 However, the Otoucalofa Creek watershed (Figure 1) is not yet under the direct threat of  
434 increased rates of development and appears to hold the largest connected population of *E.*  
435 *faulkneri* (Sterling et al.; 2012, 2013). Land use is still mostly dominated by timber plantations  
436 and row crop agriculture upstream of Water Valley. The USFWS (Jackson, MS) and USDA  
437 NRCS (Jackson, MS) have also taken steps to improve aquatic organism passage and riparian  
438 habitat in two streams in the Otoucalofa Creek watershed (NRCS, 2020; USFWS, 2020). Time  
439 possibly remains for the public to become aware that a unique part of their natural heritage  
440 swims in the streams in their backyards, on their farms, and the lands they hunt. Increased  
441 awareness may help to protect enough habitat for *E. faulkneri* to persist in the Otoucalofa Creek  
442 watershed over the coming century.

443

#### 444 *Etymology*

445 We have named the species *Etheostoma faulkneri* to honor the great writer and Nobel Laureate  
446 William C. Faulkner (1897-1962), a native of the Oxford, Mississippi area who was also an avid  
447 hunter and fisher. The landscape was an important theme in many of his works, and the actions  
448 of his characters were often influenced by the lands and streams surrounding his fictional  
449 Jefferson, Mississippi, including the Yocona River, which he renamed the Yoknapatawpha.

450

#### 451 **Discussion**

452 *Etheostoma faulkneri* masqueraded as *E. raneyi* for decades mostly because of the lack of  
453 distinctive color differences in nuptial males during spawning. Even so, patterns of distribution  
454 and quantitative differences in lateral line scale counts (Table 3), male nuptial color (Figures 4

455 and 5), length (Table 10), and morphology (Table 10; Figure 6 ) between individuals sampled  
456 from the Y.R. and L.T.R., as well as population genetic and phylogenetic data (Powers &  
457 Warren, 2009; Sterling et al.; 2012, 2020), support the recognition of *Etheostoma faulkneri* as a  
458 separately evolving metapopulation and valid species under the unified species concept (de  
459 Queiroz, 2007).

460 Species descriptions of other snubnose darters have often relied on colors of breeding males  
461 and examination of meristic and morphological characters for diagnosis. Though distinct  
462 differences in male color among closely related taxa are sometimes described (Boschung et al.,  
463 1992), subjective descriptions of color differences are likely to vary according to the source  
464 (Suttkus & Bailey, 1993). In some cases, described differences in male color are less than  
465 distinct (Suttkus et al., 1994) and are not reliable across the range of individual variation within  
466 species (see *Ulocentra* key in Boschung & Mayden, 2004). Qualitative differences in meristic  
467 and morphological characters are rare among *Adonia* snubnose darters and are limited to counts  
468 of branchiostegal rays which separate *E. coosae* from the rest of the clade (except for *E. scotti*,  
469 Bauer et al., 1995). Our results are consistent with these observations and the quantitative  
470 differences that we detected are similar to those found for other species of snubnose darters  
471 (Suttkus et al., 1994; Bauer et al., 1995; Powers & Mayden, 2003).

472 Because pigment patterns, meristics, and body shape cannot reliably distinguish individuals  
473 from the L.T.R. and Y.R., and the only diagnosable characters that qualitatively distinguish  
474 between *E. faulkneri* and *E. raneyi* are genetic (Powers & Warren, 2009; Sterling et al., 2020), it  
475 is reasonable to categorize *E. faulkneri* as a cryptic species. Cryptic species can occur through  
476 several mechanisms that are not mutually exclusive: recent divergence, phylogenetic niche  
477 conservatism, and evolutionary convergence (Fišer et al., 2017). Evolutionary convergence is

478 clearly not a factor. However, the estimated time of separation between *E. faulkneri* and *E.*  
479 *raneyi* (<1 my) is recent (Sterling et al., 2020) and niche conservatism is apparent between the  
480 two species (Johnston & Haag, 1996; Sterling et al., 2017; Ruble et al., 2019) and other snubnose  
481 darters as well (O'Neil, 1981; Carney & Burr, 1989; Hicks, 1990; Khudamrongsawat &  
482 Kuhajda, 2007; Barton & Powers, 2010; Hubbell & Banford, 2019). *Etheostoma faulkneri* and *E.*  
483 *raneyi* exist in adjacent drainages with little latitudinal gradient, no elevational gradient, and no  
484 clear differences in surface geology, water chemistry, or aquatic communities. Their Eltonian  
485 and Grinnellian niches appear to be identical in all respects but one: there is a small difference in  
486 stream size and gradient between streams that the two species inhabit. Though this difference has  
487 likely influenced the subtle morphological divergence that we detected, it is clear that in the  
488 absence of other biotic or abiotic differences between the L.T.R. and Y.R. drainages, stabilizing  
489 selection for their ancestral niche across a short time span since separation has prevented the  
490 evolution of readily observable divergent morphological, meristic, or color characters.

491 Cryptic diversity is common among diverse taxa (Pfenninger & Schwenk, 2007; Adams et al.,  
492 2014; Fennessy et al., 2016), including freshwater fishes in North America (Egge & Simons,  
493 2006; April et al., 2011). Among darters (Etheostomatinae), cryptic diversity is especially  
494 common (April et al., 2011) and is linked to niche conservatism, vicariant events and allopatric  
495 distributions, and relatively stable habitat conditions over geologic time-scales (Bauer et al.,  
496 1995; Page et al., 2003; Near & Benard, 2004; Hollingsworth & Near, 2009; Kozal et al., 2017).  
497 These conditions are consistent with the literature on *E. faulkneri* and *E. raneyi* and our results  
498 (Johnston & Haag, 1996; Powers & Warren, 2009; Sterling & Warren, 2017; Sterling et al.,  
499 2020), as they are for other *Adonia* snubnose darters (Carney & Burr, 1989; Bauer et al., 1995;  
500 Powers & Mayden, 2003; Khudamrongsawat & Kuhajda, 2007; Kozal et al., 2017).

501

**502 Conclusions**

503 The results we present here, existing genetic evidence (Powers & Warren, 2009; Sterling et al.;  
504 2012, 2020), and a growing acceptance among biologists that the presence of readily observable  
505 qualitative diagnostic characters are not necessary to describe biodiversity (Egge & Simons,  
506 2006; de Queiroz, 2007; Fišer et al., 2017), supports the recognition and description of  
507 *Etheostoma faulkneri*, the Yoknapatawpha Darter, as an independently evolving metapopulation  
508 lineage and valid species under the unified species concept (de Queiroz, 2007). The description  
509 of *E. faulkneri* represents an increase in the accuracy of our understanding of freshwater fish  
510 evolution and diversity, which is the foundation for research and conservation efforts for the  
511 many imperiled freshwater fishes of the southeastern United States.

512

**513 Acknowledgments**

514 We thank the many people who contributed to this project by assisting in the field and the lab,  
515 sharing ideas and information, and providing logistical support: S. Adams, Z. Barnett, H.L. Bart,  
516 S. Bingham, M. Bland, A. Carson, W. Haag, G. Henderson, J. Hubbell, C. Jenkins, G.  
517 McWhirter, S. Nielsen, B. Noonan, C. Sabatia, J. Schaefer, C. Smith, S. Smith, B. Sterling, W.  
518 Sterling, and M. Wagner. This study was supported by the USDA Forest Service, Southern  
519 Research Station, Oxford, MS.

## Figure 1

Map of northern Mississippi showing the distribution of *Etheostoma raneyi* (Yazoo Darter) and *E. faulkneri* (Yoknapatawpha Darter).

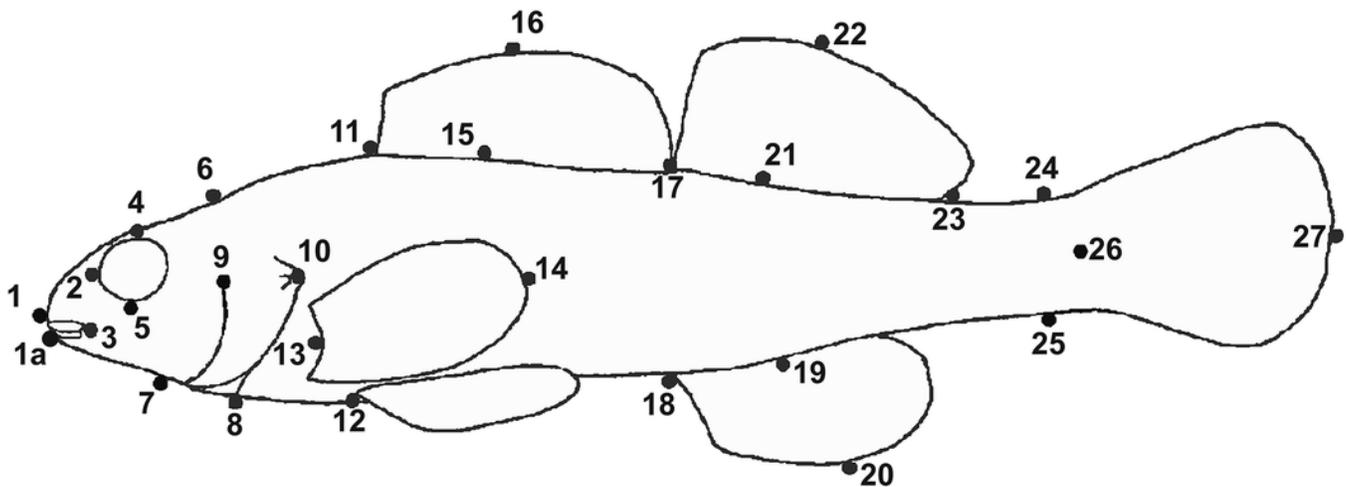

Distribution is indicated by green circles in the Little Tallahatchie River drainage (Yazoo Darter) and green triangles in the Yocona River drainage (Yoknapatawpha Darter). The location of the old confluence (blue square) of the two drainages is shown as well as the new confluence (blue diamond) after stream alterations; the approximate boundaries of the Mississippi Alluvial Plain, Lower Gulf Coastal Plain, and Upper Gulf Coastal Plain are indicated from west to east, respectively.

## Figure 2

Location of landmarks used for truss measurements is shown (after Powers & Mayden, 2003).

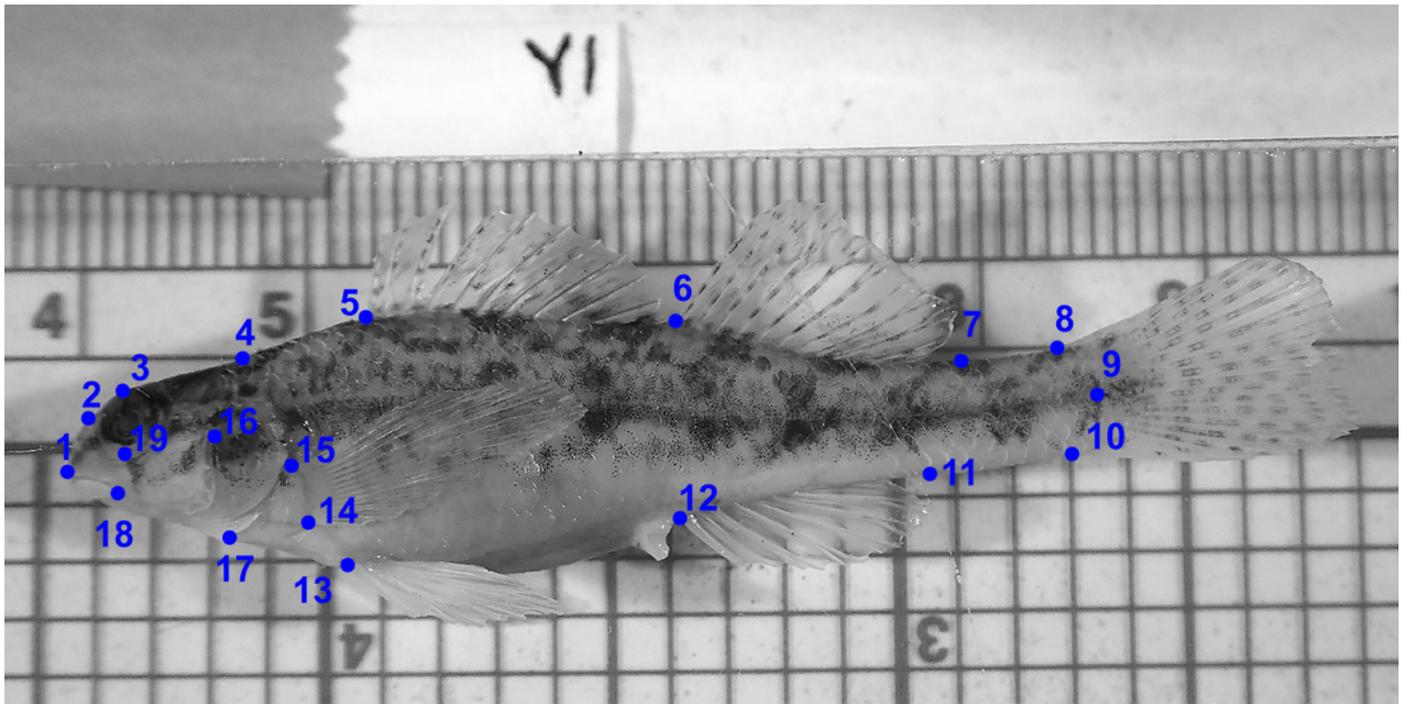

Numbers correspond to Table 10.

## Figure 3

Landmark locations used for geometric morphological analyses are shown.

The label Y1 in the photograph indicates individual number one from the Yocona River drainage.

## Figure 4

Photographs of *Etheostoma faulkneri* (Yoknapatawpha Darter) and *E. raneyi* (Yazoo Darter).

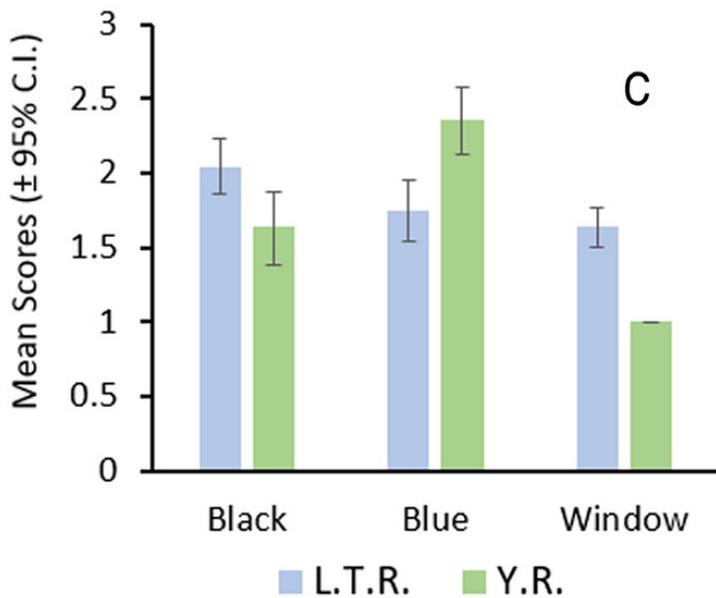

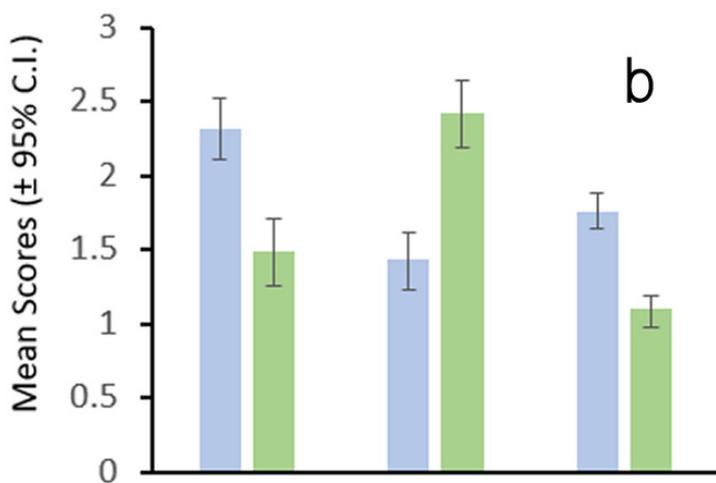

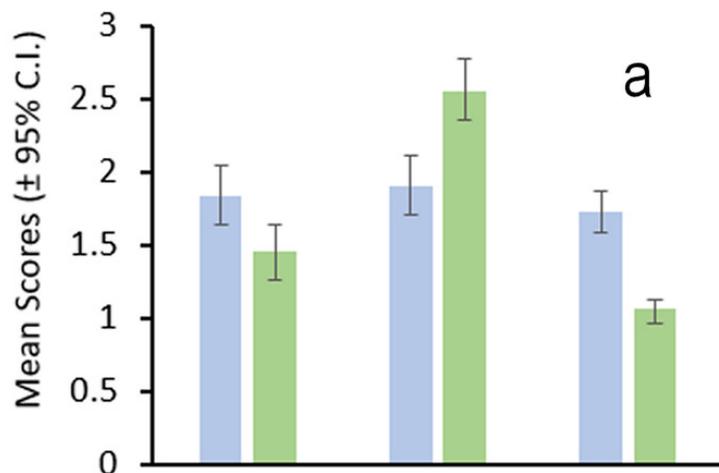

Shown are *E. faulkneri* male holotype (c) and female allotype (a) (see text for specimen data), and male (d) and female (b) *E. raneyi* for comparison; scale bar = 1 cm.

## Figure 5

Bar graph showing the results of male nuptial color surveys.

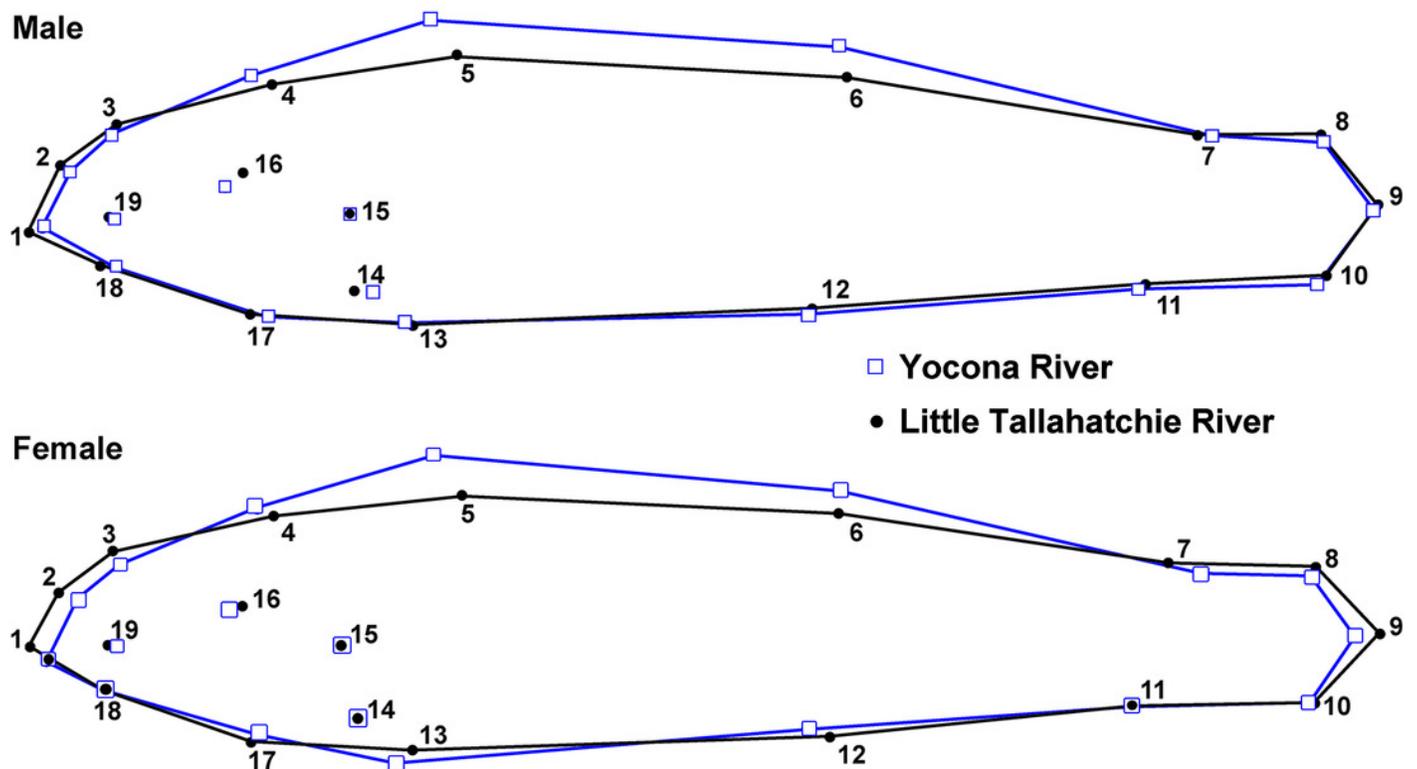

Each graph (a, b, c) represents mean values ( $\pm$  95% C.I.) scored by one of three colleagues for each character (Black, Blue, Window, see text for definitions of characters); L.T.R. = Little Tallahatchie River, n = 153; Y.R. = Yocona River, n = 108.

## Figure 6

Output from lateral view geometric morphological analyses (MorphoJ) showing shape changes for male and female *Etheostoma raneyi* and *E. faulkneri* between drainages.

Numbers represent fixed points in the analysis (see Figure 3).

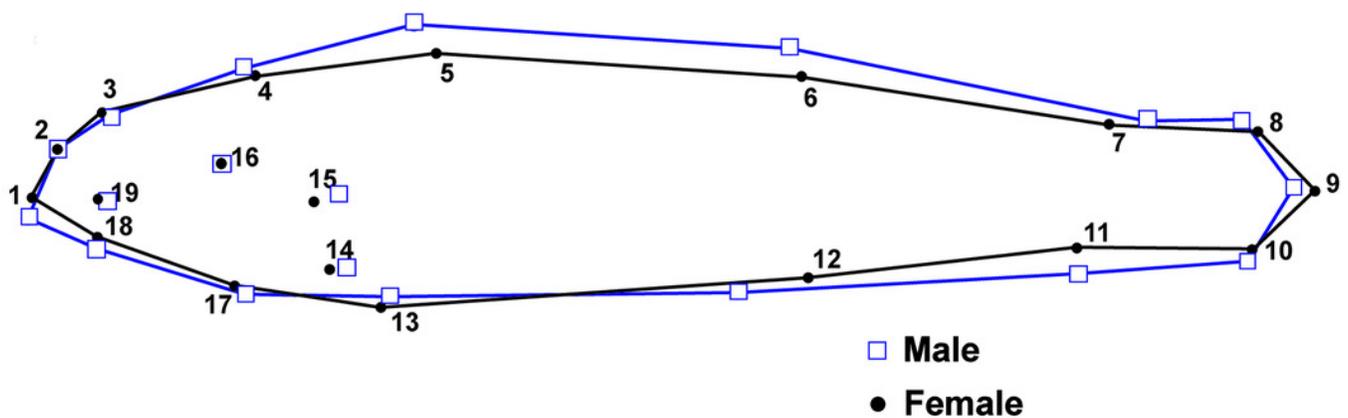

## Figure 7

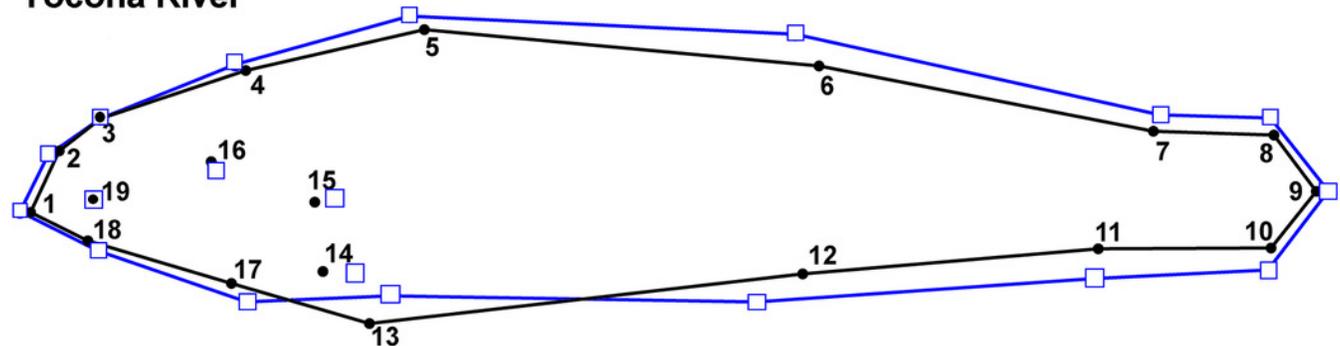

Output from lateral view geometric morphological analyses showing shape changes for male and female *Etheostoma raneyi* (Little Tallahatchie River) and *E. faulkneri* (Yocona River) between sexes within drainages.

Numbers represent fixed points in the analysis (see Figure 3).

### Little Tallahatchie River

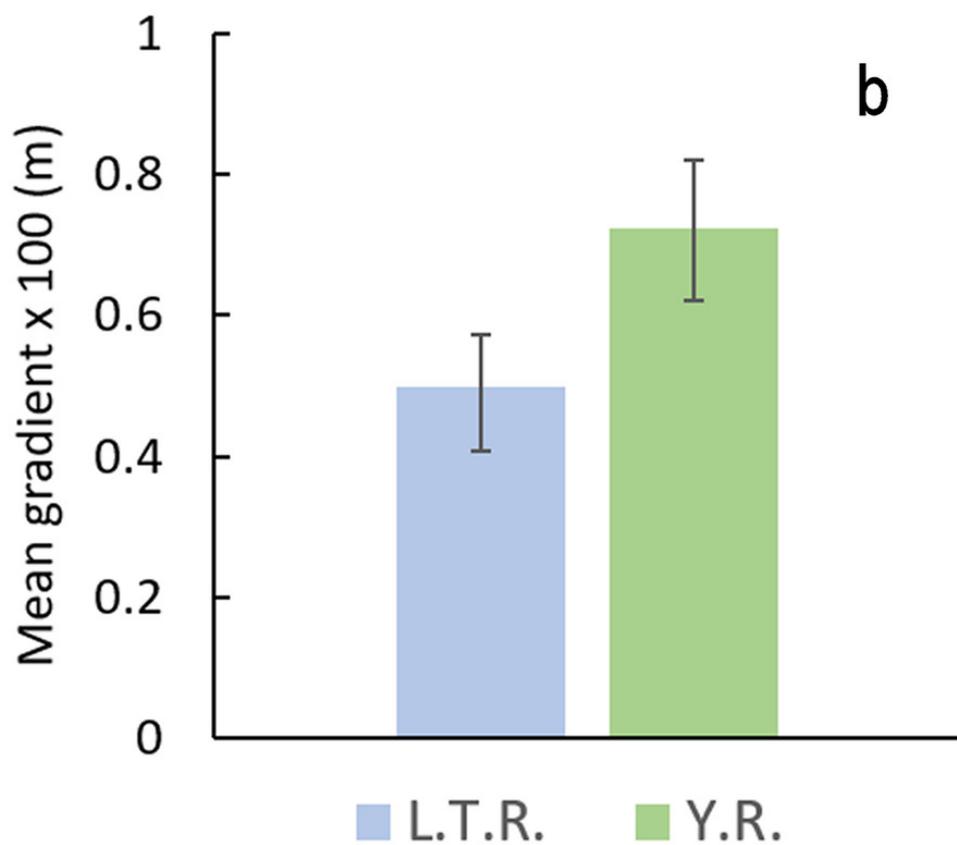

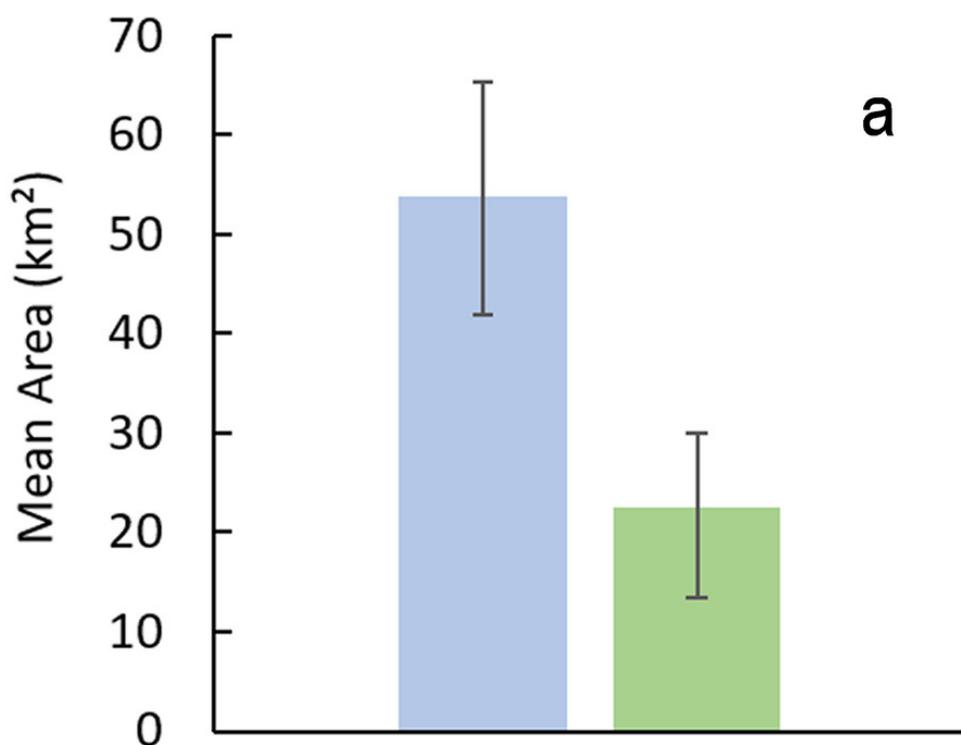

### Yocona River

## Figure 8

Mean stream gradient (b) and watershed area (a) ( $\pm$  95% C.I.) are shown for all tributary streams with *Etheostoma raneyi* and *E. faulkneri*.

Abbreviations indicate Y.R. = Yocona River and L.T.R. = Little Tallahatchie River drainages.

**Table 1** (on next page)

Specimen data used for male nuptial color comparisons is shown.

Drainage basins are indicated by L.T.R. = Little Tallahatchie River (*Etheostoma raneyi*) and Y.R. = Yocona River (*E. faulkneri*); stream name, date of sample, water temperature, and the number of males photographed are also shown.

Drainage	Stream	Date	Temp. (°C)	n	Coordinates

**Table 5**(on next page)

Compilation of frequency distributions of caudal peduncle scale counts for six species of snubnose darters and one undescribed form.

Modal counts are in bold; sources of data not cited in the table are as follows: *Etheostoma cervus* (Bailey & Etnier, 1988; Powers & Mayden, 2003; Kozal et al., 2017); *E. pyrrhogaster*, *E. zonistium*, *E. cf. zonistium*, and *E. cyanoprosopum* (Bailey & Etnier, 1988; Kozal et al., 2017); S.D. = standard deviation.

	14	15	16	17	18	19	20	n	□	S.D.
