

# Genetic approaches to the conservation of migratory bats: a case study of the eastern red bat (*Lasiurus borealis*)

Maarten Vonhof, Amy L. Russell

Documented fatalities of bats at wind turbines have raised serious concerns about the future impacts of increased wind power development on populations of migratory bat species. However, for most bat species we have no knowledge of the size of populations and their demographic trends, the degree of structuring into discrete subpopulations, and whether different subpopulations use spatially segregated migratory routes. Here, we utilize genetic data from eastern red bats (*Lasiurus borealis*), one of the species most highly affected by wind power development in North America, to (1) evaluate patterns of population structure across the landscape, (2) estimate effective population size ( $N_e$ ), and (3) assess signals of growth or decline in population size. Using data on both nuclear and mitochondrial DNA variation, we demonstrate that this species forms a single, panmictic population across their range with no evidence for the historical use of divergent migratory pathways by any portion of the population. Further, using coalescent estimates we estimate that the effective size of this population is in the hundreds of thousands to millions of individuals. The high levels of gene flow and connectivity across the population of eastern red bats indicate that monitoring and management of eastern red bats must integrate information across the range of this species.

## 24 INTRODUCTION

25 As concerns about anthropogenic climate change and the long-term environmental impacts of burning  
 26 of fossil fuels on biological and human systems have heightened, there is increasing motivation to  
 27 develop alternative sources of energy that will reduce the production of greenhouse gasses. Wind  
 28 power has become an increasingly important sector of the energy industry and is one of the fastest  
 29 growing sources of renewable energy (Kaldellis & Zafirakis, 2011; Leung & Yang, 2012). Despite the  
 30 many positive aspects of wind power development, there have been environmental costs associated  
 31 with turbine installation and operation (Morrison & Sinclair, 2004; Abbasi et al., 2014). Fatalities of  
 32 bats at wind power installations have emerged as a major environmental impact of wind power  
 33 development, with large mortality events being reported at a number of wind energy facilities in the  
 34 United States and abroad (Erickson et al., 2001; Erickson, Johnson & Young, 2005; Kunz et al., 2007;  
 35 Arnett et al., 2008). The bat species most affected by wind power in North America are migratory, tree-  
 36 roosting species such as hoary bats (*Lasiurus cinereus*), eastern red bats (*Lasiurus borealis*), and silver-  
 37 haired bats (*Lasionycteris noctivagans*), which together constitute almost three-quarters of the bat  
 38 carcasses found at wind turbines (Arnett et al., 2008). Although mortalities may occur throughout April  
 39 to November, most bat fatalities in North America have been reported in late summer and early autumn  
 40 (reviewed by Kunz et al., 2007; Arnett et al., 2008) and appear to be concentrated during fall migration  
 41 of the affected species (Cryan, 2003).

42 The observed high levels of mortality for these species at wind power installations raise  
 43 concerns about the long-term impacts of this technology on bat populations, yet we lack the necessary  
 44 information to place this mortality in context with respect to baseline population estimates and  
 45 demographic trends of the affected species. For most bat species we have no knowledge of the size of  
 46 populations and their demographic trends, the degree of structuring into discrete subpopulations, and  
 47 whether different subpopulations use spatially segregated migratory routes. While estimates of local

48 population sizes within particular roosts may be feasible using traditional capture-mark-recapture  
 49 (CMR) methodology or survey techniques, no reliable range-wide population estimates exist for any  
 50 bat species (O'Shea & Bogan, 2003; Kunz et al., 2009). Traditional demographic approaches have  
 51 limitations when applied to bats, as they are nocturnal, exhibit cryptic behavior, and are difficult to  
 52 follow over time during extensive seasonal movements between summer breeding areas and  
 53 overwintering sites (Cryan, 2003; Rivers, Butlin & Altringham, 2006). The tree-roosting migratory bat  
 54 species that are killed in high numbers at wind turbines are especially inaccessible for traditional CMR  
 55 studies, given their solitary nature and restriction to forested habitats (Kunz, 1982; Shump & Shump,  
 56 1982a,b). Large-scale banding studies typically experience extremely low recapture rates (e.g., Glass,  
 57 1982; reviewed in O'Shea & Bogan, 2003), and there are serious data deficiencies with respect to sex-  
 58 and age-specific survival and reproductive rates that hamper our ability to widely apply demographic  
 59 models to bat populations. Given these difficulties, we require other approaches to estimating  
 60 population sizes and demographic trends within migratory bat populations affected by wind power  
 61 development.

62 Genetic approaches provide an alternative to traditional demographic methods of population  
 63 estimation, and allow us to estimate the degree of population structuring, demographic trends within  
 64 subpopulations, and effective population size ( $N_e$ ) using data on allele frequencies or the base  
 65 composition of DNA sequences. Fewer individuals need to be sampled relative to CMR approaches,  
 66 and individuals need only be sampled a single time for many analyses. In addition, population  
 67 parameters can be estimated directly from the observed patterns of genetic variation, and age- or sex-  
 68 specific demographic information may not be required. Molecular markers can also be used to examine  
 69 levels of population differentiation within a species and to geographically delimit populations or  
 70 groups of populations based on the observed distribution of genetic variation (Freeland, Petersen &  
 71 Kirk, 2011). Importantly, such analyses can be used to define the relevant unit for population

72 monitoring, and highlight demographic connections among populations that may not be obvious from  
 73 behavioral data alone. As mating is likely to take place during migration in bats (Dodd & Adkins,  
 74 2007; Cryan, 2008; Cryan et al., 2012; Solick et al., 2012), gene flow should occur among populations  
 75 that interact during migration. Therefore it is likely that any genetically distinct populations, if they  
 76 exist, will be using different migratory pathways and may be subject to different mortality rates as  
 77 wind turbines are concentrated heterogeneously across the landscape. The analysis of genetic  
 78 population structure is therefore highly relevant to our understanding of bat – wind turbine interactions.

79 While it is not possible to directly estimate adult census population size ( $N_c$ ) using molecular  
 80 data (although genetic markers can be used to identify individuals for traditional CMR analyses;  
 81 Luikart et al., 2010), it is possible to estimate effective population size ( $N_e$ ).  $N_e$  is defined as the  
 82 number of individuals in an ideal Wright-Fisher population (a large, constant-sized, randomly-mating,  
 83 hermaphroditic population with discrete generations) that would lose genetic variation through genetic  
 84 drift at the same rate as the actual population (Crow & Denniston, 1988). It provides information on  
 85 how quickly genetic variation is being lost, or relatedness is increasing, in a population of interest, and  
 86 may be interpreted as an estimate of the number of individuals actually contributing genes to the next  
 87 generation. The estimation of  $N_e$  has seen wide application in studies of threatened or isolated  
 88 populations, as the magnitude of genetic drift, and hence loss of genetic variation, is inversely  
 89 proportional to  $N_e$  (Leberg, 2005; Wang, 2005; Luikart et al., 2010). Current estimates of  $N_e$  can be  
 90 used to assess the ‘genetic health’ of populations and their capability to respond to future  
 91 environmental change or anthropogenic changes via selection (Frankham, Ballou & Briscoe, 2002).  
 92 Estimation of  $N_e$  is also common in phylogeographic studies exploring past changes in population sizes  
 93 in relation to changing climatic conditions or vicariant events in the evolutionary history of species  
 94 (Avice, 2000; Russell et al., 2011), thus providing important insight into the demographic history of  
 95 populations and species.

Here, we utilize genetic data from eastern red bats (*Lasiurus borealis*), one of the species most highly affected by wind power development in North America, to (1) evaluate patterns of population structure and whether different subpopulations use spatially segregated migratory routes, (2) estimate effective population size ( $N_e$ ), and (3) assess signals of growth or decline in population size. This species was chosen because it is one of the three bat species of greatest concern with regard to the biodiversity impacts of wind energy, and has the highest fatality rate at a number of wind power installations in the eastern United States (Arnett et al., 2008). Although estimates of census population size would be preferable for understanding the size of bat populations and the potential impact of fatalities at wind power installations,  $N_e$  estimates may provide us with valuable information on the size of the evolutionarily relevant portion of the population (that portion contributing genes to the next generation). Further, regular monitoring of  $N_e$  might serve as a proxy for tracking changes in population size over time. Our study provides valuable data for understanding the population-level impacts of mortalities due to wind power for this migratory bat species by assessing whether there are discrete subpopulations that may represent independent management units and may undergo different migratory behavior, whether populations from different regions may be connected demographically, and the relative magnitude and historical population trends of the population or subpopulations we identify.

## METHODS

### Sampling

Tissue samples from eastern red bats were collected by researchers capturing bats in the field or collecting carcasses at wind power developments. We asked researchers across the range to collect samples, but eastern red bats were not encountered in all areas due to regional differences in encounter rates. Therefore, we have the largest sample sizes per site and the greatest number of samples from the

120 eastern portion of the species' range. All researchers were required to have appropriate state and  
 121 federal collecting permits. A small number of samples from Michigan were collected by one of the  
 122 authors (MJV) under permit from the state of Michigan (Michigan Department of Natural Resources  
 123 permit SC-1257) with appropriate Institutional Animal Care and Use Committee approval (Western  
 124 Michigan University protocol 05-03-01).

125       We compiled a collection of tissue samples from known sample sites collected in the summer  
 126 months (June to mid-August when bats are likely to be resident) primarily between 2000-2006, for the  
 127 purpose of assessing levels of genetic population structure and estimating  $N_e$  (Table 1, Table S1). We  
 128 received tissue samples for 1 – 39 bats from any given site. We had sufficient sample size ( $N > 15$ ) for  
 129 each of 12 sites with which to carry out site-level population genetic analyses (Figure 1, Table 1).  
 130 Unlike colonial bats roosting in buildings or trees where bats can be captured in numbers from a single  
 131 point location during a single sampling session, tree-roosting bats such as eastern red bats are solitary.  
 132 Sampling these bats therefore must involve the capture of foraging individuals and may encompass  
 133 individuals from a wider area over a longer time scale. Therefore we define a 'site' as a collection of  
 134 capture localities within a set of nearby counties within a single state or province. For six of our sites,  
 135 bats were captured either within a single county or at a single capture location (AR, GA, MO, ON, TX,  
 136 WV-Ma), while the other six sites consisted of individuals captured in several counties within a given  
 137 state (IL, MD, MI, NC, TN, WV-Pe; the site label for the latter site represents one of the two counties  
 138 included; Table S1). There were no consistent differences in diversity measures within sites or levels of  
 139 differentiation between sites associated with sites containing samples from a single versus multiple  
 140 counties (see Results).

## 141 **Laboratory Methods**

142 Analyses of population genetic structure were carried out by analyzing variation at microsatellite loci  
 143 and mtDNA sequences.  $N_e$  estimation was carried out using these same markers, as well as sequences

144 from a nuclear intron marker. All but one analysis (msvar; see below) used this primary set of marker  
145 data.

146 DNA was extracted from samples using a DNEasy Tissue Extraction Kit (Qiagen). Sixteen  
147 variable microsatellite loci were genotyped for all individuals used in site-level analyses ( $N = 284$ )  
148 using primers developed specifically for eastern red bats (primers Lbo-B06, C07, D08, D200, D202,  
149 D203, D204, D226, D240, D245, and D248; Eackles & King, pers. comm.), as well as primers  
150 originally developed for other bat species (MS3E10 and MS1C01, Trujillo & Amelon, 2009; IBat-  
151 Ca22 Oyler-McCance & Fike, 2011; Cora\_F11\_C04, Piaggio, Figueroa & Perkins, 2009; and  
152 Coto\_G12F\_B11R, Piaggio et al., 2009). Loci were multiplexed whenever possible; all PCR reactions  
153 combined varying amounts of each primer and 2  $\mu$ L template DNA with an illustra PuReTaq ready-to-  
154 go PCR bead (GE Health Care) to a total volume of 25  $\mu$ L (Table S2). The basic cycling conditions  
155 consisted of 1 min at 94 °C, three cycles of 30 sec at 94 °C, 20 sec at  $T_a$  (54 or 60 °C), and 5 sec at  
156 72 °C, 33 cycles of 15 sec at 94 °C, 20 sec at  $T_a$ , and 10 sec at 72 °C, followed by a final extension  
157 at 72 °C for 30 min. Some amplifications required additional cycles or the removal of the final  
158 extension step (Table S2). Multiple PCR reactions were subsequently pooled for loading on an  
159 ABI3130 Sequencer at the Vanderbilt University DNA Sequencing Facility for fragment analysis (see  
160 Table S2 for information on multiplexes and loads used), and visualized and scored using GeneMarker  
161 software (SoftGenetics).

162 A fragment of the hypervariable 2 portion of the mitochondrial DNA control region (hereafter  
163 HV2) was sequenced from 218 individuals used in site-level analyses (because of financial constraints  
164 not all individuals from each location and not all locations were sequenced; Table 1), as well as 77 bats  
165 from 30 additional locations that were not included in site-level analyses, for a total of 295 individuals  
166 sequenced. Amplification of HV2 was initially carried out using the reverse complement of primer F

from Wilkinson & Chapman (1991; RevF: 5'-CTA CCT CCG TGA AAC CAG CAA C-3') sitting in the central conserved sequence block as the forward primer, and the primer sH651 located in the tRNA<sub>Pro</sub> gene (Castella, Ruedi & Excoffier, 2001) as the reverse primer. However, these primers span a region containing a large stretch of 6 bp repeats, resulting in a large amplicon of 1500-2000 bp. We therefore designed a new reverse primer (LABO-HV2R2: 5'-TCC TGT WAC CAT TAA YTA ATA TGT CCC-3') that amplified a 408 bp fragment excluding the repeats. Amplification was carried out using the above reaction conditions and the cycling conditions in Castella, Ruedi & Excoffier (2001) with a  $T_a$  of 60 °C. PCR reactions were cleaned using ExoSAP-IT (PCR Product Pre-Sequencing Kit, Affymetrix), and sent to the University of Arizona Genetics Core for bi-directional sequencing. Sequences were edited using CodonCode Aligner software (CodonCode Corporation). All unique HV2 haplotypes are deposited in Genbank (accession numbers KR337091 - KR337257; Table S1).

We further sequenced a 612 bp fragment of the nuclear Chymase intron 4 (CHY) for a random subset of 88 individuals. Based on our results indicating panmixia across the sampled range of eastern red bats (see Results), a random sample of individuals should represent genetic variation found in the wider population (Felsenstein, 2006). This reduced subsample was chosen because the methods used for  $N_e$  estimation are computationally intensive, and analysis would not have been possible with a larger sample of sequences. CHY was amplified through PCR using the primers Chy-F (5'-GTC CCA CCT GGG AGA ATG TG-3') and Chy-R (5'-TGG GAG ATT CGG GTG AAG-3'; Venta et al., 1996). The reaction conditions were identical to those for the microsatellite loci, except that the reaction used just 1 µL of template. The temperature profile included an initial extended denaturation of 95 °C for 5 minutes, followed by 40 cycles of 95 °C for 1 minute, 52 °C for 1 minute and 72 °C for 1.5 minutes, with a final extension step at 72 °C for 4 minutes. The PCR reaction was cleaned using a PCR purification kit (Qiagen) and sent to the University of Arizona Genetics Core for bi-directional sequencing using the Chy-F and Chy-R primers. These diplotypes were edited and heterozygous sites

191 called using Sequencher v.4.8 (GeneCodes).

192       Some individuals ( $N = 36$ ) found to contain two or more heterozygous sites were cloned using  
 193 the TOPO TA cloning kit (Life Technologies) following manufacturer's instructions. Six to eight  
 194 colonies were picked for each cloned individual. The picked colonies were each suspended in 10  $\mu$ L  
 195 dH<sub>2</sub>O and heated to 95°C for 10 minutes to lyse the cells. The cell lysate was then used directly as  
 196 template DNA for colony screening through PCR. The PCR reaction combined 10 ng of each primer  
 197 and 10  $\mu$ L cell lysate with an illustra PuReTaq ready-to-go PCR bead (GE Health Care) to a total  
 198 volume of 25  $\mu$ L. The temperature profile followed that described above for the initial cloned PCR.  
 199 PCR reactions yielding amplicons of the expected size (~650 bp) were cleaned using ExoSAP-IT  
 200 (Affymetrix) following the manufacturer's instructions. Cleaned PCR amplicons were then sent to the  
 201 University of Arizona Genetics Core for bi-directional sequencing using the Chy-F and Chy-R primers.  
 202 Based on these experimentally-resolved haplotypes, another 44 individuals with ambiguous diplotypes  
 203 were computationally phased using Phase v.2.1.1 (Stephens, Smith & Donnelly, 2001; Stephens &  
 204 Donnelly, 2003) with a confidence threshold of 0.95. All unique CHY haplotypes are deposited in  
 205 Genbank (accession numbers KR362302 - KR362477; Table S1).

## 206 **Analysis of Genetic Structure**

207 For microsatellite genotypes, deviations from Hardy-Weinberg equilibrium (HWE) at each locus were  
 208 estimated using GENODIVE (Meirmans, 2012), and loci were confirmed to be in linkage equilibrium  
 209 using FSTAT v.2.9.3 (Goudet, 1995). Null allele frequencies for each locus were estimated in  
 210 CERVUS v.3.1 (Kalinowski, Taper & Marshall, 2007). To test for differences among sites in levels of  
 211 genetic diversity, several indices of nuclear genetic diversity were estimated, including number of  
 212 alleles per locus, allelic richness, and the inbreeding coefficient ( $F_{IS}$ ) using FSTAT, private allelic  
 213 richness using HP-RARE 1.0 (Kalinowski, 2005), and observed and expected heterozygosity using

214 GENODIVE. We then tested for differences among sites (or groups of sites) in allelic richness, and  $F_{IS}$   
215 in FSTAT, and expected heterozygosity in GENODIVE, using 10,000 permutations.

216 Different clustering algorithms can produce different solutions, and concordance among  
217 multiple techniques is suggestive of the presence of a strong genetic signal (Guillot et al., 2009).  
218 Therefore, we applied two different approaches to determine the most likely number of distinct genetic  
219 clusters independent of original sampling locations. First, we utilized the model-based Bayesian  
220 clustering approach in STRUCTURE v.2.3.3 software (Pritchard, Stephens & Donnelly, 2000; Falush,  
221 Stephens & Pritchard, 2003) with population membership as a prior (Hubisz et al., 2009). To determine  
222 the optimal number of clusters ( $K$ ), we ran 10 runs per  $K$ , for  $K = 1-10$ , each with an MCMC search  
223 consisting of an initial 100,000-step burn-in followed by 400,000 steps using the admixture model with  
224 correlated allele frequencies. The most likely number of clusters was determined using the Evanno,  
225 Regnaut & Goudet (2005) method implemented in the program STRUCTURE HARVESTER (Earl &  
226 vonHoldt, 2012). The Evanno, Regnaut & Goudet (2005) method is not informative for the highest and  
227 lowest  $K$  values; therefore, if the highest log likelihood value was observed for  $K = 1$  or 10 across all  
228 replicates, we accepted that as the best-supported value of  $K$ .

229 Second, we applied the repeated allocation approach of Duchesne & Turgeon (2009, 2012)  
230 implemented in the software FLOCK. In this method, samples are initially randomly partitioned into  $K$   
231 clusters ( $K \geq 2$ ), allele frequencies are estimated for each of the  $K$  clusters, and each genotype is then  
232 reallocated to the cluster that maximizes the likelihood score. Repeated reallocation based on  
233 likelihood scores (20 iterations per run) results in genetically homogeneous clusters within a run  
234 (Duchesne & Turgeon, 2012). Fifty runs were carried out for each  $K$ , and at the end of each run the  
235 software calculated the log likelihood difference (LLOD) score for each genotype (the difference  
236 between the log likelihood of the most likely cluster for the genotype and that of its second most likely  
237 cluster) and the mean LLOD over all genotypes. Strong consistency among runs (resulting in ‘plateaus’

238 of identical mean LLOD scores) is used to indicate the most likely number of clusters (Duchesne &  
239 Turgeon, 2012).

240 The level of genetic differentiation among pre-defined sites ( $N = 12$ ; Table 1) based on  
241 microsatellites was determined by calculating pairwise distance measures, including  $F_{ST}$  (Weir &  
242 Cockerham, 1984) in ARLEQUIN v.3.11 (Excoffier, Laval & Schneider, 2005), and a measure  
243 independent of the amount of within-site diversity (Jost's  $D$ ; Jost, 2008) in GENODIVE. We tested for  
244 significance of pairwise  $F_{ST}$  values between sites with 10,000 permutations, and performed an analysis  
245 of molecular variance (AMOVA; Excoffier, Smouse & Quattro, 1992) to describe the relative amount  
246 of genetic variation within and among sites in ARLEQUIN.

247 To describe overall levels of mtDNA diversity within sites, we calculated haplotype ( $h$ ) and  
248 nucleotide ( $\pi$ ) diversities in DnaSP v.5.10.1 (Librado & Rozas, 2009). We calculated pairwise  $F_{ST}$   
249 values between sites and tested for significance with 10,000 permutations in ARLEQUIN to identify  
250 pairs that were genetically distinct. As with microsatellite genotypes, we performed an AMOVA on  
251 HV2 haplotype frequencies in ARLEQUIN.

## 252 **Estimation of $N_e$**

253 We used a number of approaches to estimate  $N_e$  for eastern red bats. Although we originally set out to  
254 estimate the short-term variance effective population size ( $N_{ev}$ , Crandall, Posada & Vasco, 1999), it  
255 quickly became apparent that  $N_e$  was very large (see Results). This constraint precluded the use of  
256 single sample estimators based on linkage disequilibrium or summary statistics (Waples & Do, 2009;  
257 Waples & Do, 2010; Tallmon, Luikart & Beaumont, 2004; Tallmon et al., 2008), which are only  
258 effective for  $N_e < 1,000$ , or temporal methods (e.g., Jorde & Ryman, 1995), which are based on  
259 changes in allele frequencies due to genetic drift between time points (as drift is negligible with large  
260  $N_e$ ). Furthermore, the cohort-based demographic data required for the Jorde & Ryman (1995) method

were simply not available for any bat species.

Therefore, we focused on coalescent analyses, using three primary methods to estimate long-term inbreeding effective population size ( $N_{el}$ , Crandall, Posada & Vasco, 1999). These methods utilize different types of data, and therefore provide complementary estimates based on differences in the mutation rates of the markers used and differences in the underlying models assumed.

## 1. IMA2

We used the coalescent-based software IMA2 (release date 27 August 2012; Hey, 2010a, b) to estimate the effective size of the panmictic eastern red bat population (see Results). The analysis included the CHY and HV2 sequences and 16-locus microsatellite genotypes. One hundred microsatellite genotypes (= 200 chromosomes) for each locus were subsampled at random out of the full dataset in order to reduce the computational time of the analysis. The DNA sequence data (CHY and HV2) were edited to conform to an infinite sites model of mutation; microsatellite data were analyzed assuming a single-step model of mutation.

In the IMA2 analysis, we modified the underlying population model to consider only a single population, with a uniform prior on the size of that population varying from  $\theta = 0.05$  to 99.95. We ran 40 heated chains for an initial burn-in of ~3.6 million steps, followed by an MCMC search of ~10.2 million steps. Stationarity of the search chains was validated by monitoring ESS values.

## 2. Lamarc

We used the software package Lamarc v.2.1.8 (Kuhner, 2006) to estimate effective population size and population growth rates independently for the nuclear CHY and the mitochondrial HV2 sequence data. We considered a model of a single panmictic population that undergoes population size change (growth or decline) until it reaches the current population size. We implemented a Bayesian analysis in Lamarc with priors on  $\theta$  ranging from  $10^{-5}$  to 50 and on the population size change parameter ( $g$ ) ranging from -500 to 2000. The data were analyzed in three independent runs, with each

run consisting of an MCMC search that was 20 million steps long and sampled every 200 steps. The first 2 million steps were discarded as a burn-in. Each MCMC search was run as 3 heated chains, with relative heating temperatures of 1, 1.5, and 3, and each search was replicated three times internally within each of the independent runs. Posterior distributions for each independent run and for overall results per locus were visualized using Tracer v.1.5. Results are reported as median point estimates with 95% confidence intervals. All parameter estimates were well supported, with ESS values exceeding 100 in all cases.  $N_e$  was calculated from the estimated coalescent-scaled parameter  $\theta$  using the equations:  $\theta = N_e\mu$  for mitochondrial data and  $\theta = 4N_e\mu$  for autosomal data, where  $N_e$  is the effective size of the entire population. This software uses mutation rates in units of substitutions per site per generation; based on the relative mutation rates estimated for the same data in the IMA2 analysis, we used a mutation rate of  $4.29 \times 10^{-8}$  per site per generation for the HV2 dataset and  $7.76 \times 10^{-9}$  per site per generation for the CHY dataset.

### 3. msvar

The third approach we used was the coalescent-based software msvar v.1.3 (Beaumont, 1999), which estimates effective population size and demographic trends from microsatellite genotype data. This analysis considers a model in which a single ancestral population of size  $N_A$  experiences exponential population size change beginning at time  $t$  until the population reaches the current size  $N_1$ . Unlike IMA2 and Lamarc, which calculate only long-term average  $N_e$ , msvar separately calculates current and ancestral  $N_e$ . Therefore, rather than use the microsatellite genotypes included in all other site-level analyses (which spanned a multi-year period), we generated microsatellite genotypes following the methods outline above for two specific years for which we had sufficiently large sample size (2002:  $N = 353$  and 2010:  $N = 226$ ). These datasets were analyzed separately to determine whether mortality over that time interval had a measurable effect on estimates of  $N_e$ . Samples of genotypes for 2002 and 2010 were each comprised of a mixture of individuals of known summer origin, as well as

309 bats of unknown origin killed at wind power developments during fall migration.

310 To make the msvar analysis computationally feasible, we randomly subsampled 100 diploid  
311 individuals from each time point (2002 and 2010). Subsampling was performed twice, producing  
312 subsamples A and B for each time point, to ensure that no bias was introduced through subsampling.  
313 Each analyzed dataset thus included 100 sixteen-locus genotypes (= 200 chromosomes) from a single  
314 year (2002 or 2010).

315 The msvar analysis requires the specification of hyperpriors for each of the four parameters,  $N_1$ ,  
316  $N_A$ ,  $t$ , and the mutation rate  $\mu$ . These hyperpriors describe distributions from which the locus-specific  
317 initial parameter values are drawn, and are given here as  $[\log_{10}(N_1), \log_{10}(N_A), \log_{10}(\mu), \log_{10}(t)]$ . The  
318 parameter means were assumed to be normally distributed with means (7, 7, -3.5, 4.3) and standard  
319 deviations (3.5, 4, 0.5, 2). We chose these values for (1)  $N_1$  based on estimates of  $N_e$  for eastern red  
320 bats from our own Lamarc analyses with a relatively large standard deviation to reflect our own  
321 uncertainty regarding this parameter, (2)  $N_A$  based on a null hypothesis of no change in population size  
322 with a larger standard deviation to accommodate increased uncertainty in historical parameters, (3)  $\mu$   
323 based on Storz & Beaumont's (2002) msvar analysis of microsatellite variation in *Cynopterus* fruit  
324 bats, and (4)  $t$  based on a hypothesis of population size change associated with the Last Glacial  
325 Maximum with a relatively large standard deviation to reflect our own uncertainty regarding this  
326 parameter. The parameter standard deviations were assumed to be normally distributed with means (0,  
327 0, 0, 0) and standard deviations (0.5, 0.5, 2, 0.5). The means of the parameter standard deviations were  
328 set to 0 to start the search algorithm with no inter-locus variation; the standard deviations of the  
329 parameter standard deviations followed recommendations of Storz & Beaumont (2002). Each of the  
330 four datasets (2 time points, with 2 subsamples each) were analyzed 2-3 times, with each run lasting  
331 ~750 million to 2 billion steps and output logged every 100,000 steps. The initial 10% of the MCMC  
332 chains from each run were excluded as a burn-in.

333

## 334 **RESULTS**

### 335 **Genetic Structure**

336 All microsatellite loci were unlinked and the majority of loci met HWE expectations in most  
 337 populations. MS3E10 was out of HWE in 2 of 12 sites (MO, ON), IBat Ca22 in 2 sites (GA, IL),  
 338 LboD202 in one site (AR), LboD204 in one site (WV-Pe), and LboD226 in 3 sites (GA, MI, WV-Ma).  
 339 Mean observed and expected heterozygosities within sites were high (0.82 and 0.88, respectively), as  
 340 was the mean number of alleles per locus (14.77) and allelic richness (12.92), although private allelic  
 341 richness was low (0.78; Table 1), and there were no significant differences among sites in allelic  
 342 richness,  $F_{IS}$ , or expected heterozygosity ( $P > 0.05$  in all cases). Diversity statistics per locus are  
 343 presented in Table S3. Null allele frequencies per locus were generally low and  $< 0.1$ , except for locus  
 344 LboD226 with a frequency of 0.123 (Table S3).  $F_{ST}$  estimates with null alleles are unbiased in the  
 345 absence of population structure (Chapuis & Estoup, 2007), and removing loci that failed to meet HWE  
 346 in some sites from the analyses made no difference in our conclusions; therefore we present analyses  
 347 with all loci included.

348 AMOVA analysis of microsatellite genotypes indicated an almost complete lack of structure  
 349 ( $F_{ST} = 0.0044$ ,  $P < 0.001$ ), with pairwise  $F_{ST}$  and Jost's  $D$  values between populations consistently low  
 350 and non-significant (Table 2;  $F_{ST}$  range: -0.005 – 0.009; Jost's  $D$  range: -0.036 – 0.068). Log likelihood  
 351 values for  $K = 1$  and  $K = 2$  in the Bayesian clustering method (STRUCTURE) were nearly identical  
 352 (Table S4), and there was no basis upon which to conclude that the most likely number of clusters was  
 353 different from  $K = 1$  given the low  $F_{ST}$  values among all sampled sites. Similarly, the repeated  
 354 reallocation clustering method (FLOCK) failed to reach a plateau for any  $K > 1$ , indicating  $K = 1$  as the  
 355 most likely number of genetic clusters.

356 We observed 167 unique haplotypes representing 84 segregating sites among the 295  
 357 individuals sequenced at the mitochondrial HV2 locus. The number of haplotypes per site ranged from  
 358 13-23 (mean = 18.6), and haplotype diversity ( $h$ , mean = 0.986, range = 0.961 – 1) was high for all  
 359 sites (Table 1). However, nucleotide diversity ( $\pi$ , mean = 0.011, range = 0.009 – 0.016) was relatively  
 360 low for all sites (Table 1). AMOVA analysis indicated very low levels of mitochondrial differentiation  
 361 among sites ( $F_{ST} = 0.0113$ ,  $P < 0.05$ ; 1.13% of the variation is explained by differences among  
 362 sampling sites, and 98.87% of the variation occurs within sites). Accordingly, pairwise  $F_{ST}$  values  
 363 among sites were consistently low and ranged from -0.03 – 0.049 (Table 3), with only two significant  
 364 values (between the IL and MO and the IL and TX sites).

#### 365 **$N_e$ Estimation**

366 We used three coalescent methods to estimate  $N_e$  for eastern red bats: IMa2, Lamarc, and msvar. These  
 367 methods utilize different suites of data (microsatellites only for msvar, nuclear and mitochondrial  
 368 sequence data only for Lamarc, all three data types for IMa2), and therefore were expected to provide  
 369 complementary estimates based on differences in the mutation rates of the markers used and  
 370 differences in the underlying models assumed.

#### 371 *IMa2*

372 This analysis converged on an unambiguous, unimodal posterior distribution for the single population  
 373 parameter  $\theta$  ( $= 4N_e\mu$ ) for the panmictic eastern red bat population. The most probable value of  $\theta$  was  
 374 estimated to be 37.95 (95% CI: 32.15 – 45.55). We used Pesole et al.'s (1999) estimate of mammalian  
 375 mitochondrial mutation rates ( $= 2.740 \times 10^{-8}$  substitutions per site per year) to calculate locus-specific  
 376 mutation rates for our data. The geometric mean of these rates ( $= 8.03 \times 10^{-6}$  substitutions per locus per  
 377 year  $= 1.61 \times 10^{-5}$  substitutions per locus per generation; Table S5) was used to convert coalescent-

378 scaled estimates of  $\theta$  into estimates of  $N_e$ . Our analysis thus supports an effective population size of  
379 approximately  $5.91 \times 10^5$  individuals (95% CI:  $5.00 - 7.09 \times 10^5$ ; Figure 3).

380 *Lamarc*

381 We used coalescent-based analyses in Lamarc to provide estimates of  $\theta$  and population growth  
382 independently for the nuclear CHY and mitochondrial HV2 loci. Analyses of both markers provided  
383 unambiguous, unimodal posterior probability distributions for both parameters. Utilizing the relative  
384 mutation rates estimated from IMA2, estimates of  $N_e$  using HV2 across three runs in Lamarc were  $5.18$   
385  $\times 10^5$  (95% CI:  $4.25 - 7.22 \times 10^5$ ; Table 4). The estimate of  $N_e$  using CHY (males and females) was  
386 significantly larger, with a mean of  $1.52 \times 10^6$  (95% CI:  $1.05 - 2.18 \times 10^6$ ; Table 4). There was a clear  
387 signal of historical population growth recovered from both loci (Table 4); however, the time scale over  
388 which this growth occurred is not estimated in the Lamarc model.

389 *msvar*

390 Although we found considerable variation from run to run, there were some clear patterns that emerged  
391 from these analyses. Importantly, we found no consistent difference between parameter estimates from  
392 the 2002 vs. 2010 time points (Figure 2; Figures S1-S2). We also found no consistent difference  
393 between independent subsamples (A vs. B, each run 2-3 times) of the full dataset (runs A1-A3 vs. B1  
394 and B3 for 2002; runs A1-A3 vs. B1-B3 for 2010). For the current effective population size  $N_1$ , we  
395 recovered generally consistent estimates on the order of  $10^4$ - $10^5$  (average  $N_1 \approx 74,500$ ). Estimates of  
396 ancestral effective population size  $N_A$  were less consistent among runs, but did result in estimates  
397 ranging in the same order of magnitude as  $N_1$  (average  $N_A \approx 194,300$ ; Figure S1). These analyses  
398 yielded differing signals of population growth vs. decline between runs (Table 5), although a majority  
399 of runs (8 of 11) support a model of population decline rather than growth. The time of this population  
400 size change ( $t$ ) was also variable among runs, but generally was on the order of  $10^3$ - $10^4$  years (average  $t$

401  $\approx 21,600$  years; Table 5, Figure S2). While the time of population size change is difficult to pinpoint  
402 with great accuracy, these analyses clearly are not informative regarding very recent population size  
403 change.

404

## 405 **DISCUSSION**

406 We observed extremely low levels of population structure and effective panmixia across the sampled  
407 sites for eastern red bats using both nuclear and mitochondrial DNA markers. Furthermore, there is no  
408 evidence for the historical use of different migratory pathways and no evidence for any barriers to gene  
409 flow among any of the sampled localities. Few geographic barriers to the movement of vagile  
410 organisms such as bats exist east of the Rocky Mountains, and therefore there are likely few  
411 impediments to the movement of individuals across the landscape. Phylogeographic studies of  
412 widespread bats and birds have shown low levels of genetic differentiation among eastern North  
413 American populations (Gibbs, Dawson & Hobson, 2000; Kimura et al., 2002; Jones et al., 2005;  
414 Turmelle, Kunz & Sorenson, 2011; Irwin, Irwin & Smith, 2011; but see Miller-Butterworth et al.,  
415 2014). When present, genetic structure in these species is often restricted to broad-scale differentiation  
416 between eastern and western populations on either side of the Rocky Mountains. In the case of eastern  
417 red bats, evidence from museum records indicates that they most likely migrate from northern parts of  
418 their range to the southeastern United States (Cryan, 2003) where they roost in trees during warmer  
419 periods and may hibernate beneath leaf litter for short durations during colder temperatures (Saugey et  
420 al., 1998; Moorman et al., 1999; Mormann & Robbins, 2007). However, there are summer resident  
421 populations in the southeastern United States that likely do not migrate, and it is possible that there is  
422 variation in migratory tendency across the range of eastern red bats, much like tricolored bats  
423 (*Perimyotis subflavus*; Fraser et al., 2012). Mating likely takes place before or during migration in  
424 eastern red bats (Dodd & Adkins, 2007; Cryan, 2008; Cryan et al., 2012; Solick et al., 2012), and can

take place before bats hibernate or during warm periods on the wintering grounds. Thus, the potential for mating, and hence gene flow, among individuals that spent their summers in geographically disparate areas during migration or on the wintering grounds is likely very high.

In most colonial temperate bat species, females are philopatric to natal nursery colonies or undergo short dispersal distances to nearby colonies while mating takes place during swarming and/or hibernation at distant sites that act as hotspots of gene flow between bats occupying distant roosts during the summer (Kerth et al., 2003; Veith et al., 2004; Furmankiewicz & Altringham, 2007). As a consequence, levels of mitochondrial differentiation (indicative of female movements) are often quite high among summer maternity colonies while levels of nuclear differentiation (indicative of gene flow through mating) are typically low (Castella, Ruedi & Excoffier, 2001; Bilgin et al., 2008; Kerth et al., 2008; Vonhof, Strobeck & Fenton, 2008; Bryja et al., 2009; Lack, Wilkinson & van den Bussche, 2010; Turmelle, Kunz & Sorenson, 2011). Eastern red bats and other members of the genus *Lasiurus* roost solitarily in foliage during the summer (Shump & Shump, 1982a,b), and if they exhibited philopatry it would likely occur within broader landscape units such as forest patches or stands rather than a single roost. The absence of significant mitochondrial differentiation among samples of eastern red bats suggests that females may be exhibiting high levels of dispersal, and that gene flow likely takes place via both male and female movements and mating (e.g., Russell, Medellín & McCracken, 2005; Vonhof, Strobeck & Fenton, 2008).

Before undertaking our study, we had no prior knowledge of whether the eastern red bat was divided into a series of discrete subpopulations, possibly undertaking migration along different pathways and possibly varying in size, or whether it functioned as a single, panmictic population of unknown size. Our estimates of  $N_e$  varied considerably (over an order of magnitude) among the different approaches we used, ranging from  $7.45 \times 10^4$  based on microsatellite genotypes only (msvar),

448 to  $1.52 \times 10^6$  for sequence data only (CHY in Lamarc), with intermediate estimates of  $5.18 \times 10^5$  for  
 449 HV2 (Lamarc) and  $5.91 \times 10^5$  using all markers combined (IMa2). This variation is the result of  
 450 methodological differences among the approaches we used, which all utilize different aspects of the  
 451 data and make varying assumptions about the underlying historical population processes that may have  
 452 occurred. Further, the analyses each used different marker data, which vary in their mutation rates, and  
 453 so are providing estimates across varying time scales. Nevertheless, in combination with the results of  
 454 population structure analyses, our data indicate that eastern red bats form a single, large, panmictic  
 455 population across their range and that minimum effective population sizes are likely in the hundreds of  
 456 thousands.

457       The parameter most relevant to management of this species, the actual number of individuals in  
 458 the population ( $N_c$ ), is not obtainable from our estimates of  $N_e$ . A variety of factors may reduce  $N_e$   
 459 relative to  $N_c$ , including fluctuations in population size over time, overlapping generations, and  
 460 variation among individuals in reproductive success. Attempts have been made to compare estimates of  
 461  $N_e$  to  $N_c$ , and across a wide range of organisms the average  $N_e / N_c$  ratio is 0.11 – 0.14 (Frankham,  
 462 1995; Palstra & Ruzzante, 2008); for mammals alone, the average ratio is 0.34 (Frankham, 1995). If we  
 463 applied this latter mean ratio (0.34) to our point estimates of  $N_e$ , we would obtain  $N_c$  estimates of  $2.19$   
 464  $\times 10^5$  to  $4.5 \times 10^6$  individuals. However, there are a number of serious problems with the use of our  
 465 coalescent estimates in this way.  $N_e$  is a theoretical concept that relates the genetic characteristics of a  
 466 population to those expected of an ideal population under a Wright-Fisher model. We can evaluate  $N_e$   
 467 as a measure of the evolutionary potential of populations, but there is no clear relationship between  
 468 current demography and changes in genetic variation that influence coalescent estimates of  $N_e$ . Further,  
 469 there are a number of methodological concerns. First,  $N_e$  has most often been estimated for very small  
 470 populations of less than 1,000 individuals, and we do not know how the  $N_e / N_c$  ratio may vary with the

471 magnitude of  $N_c$ . Second, the majority of the ratios provided by Frankham (1995) utilize demographic,  
 472 rather than genetic, estimates of  $N_e$ , and demographic estimates may differ substantially from genetic  
 473 estimates even when population sizes are small (Luikart et al., 2010). Third, the majority of estimates  
 474 in Frankham (1995) come from organisms with very different life histories than bats, and we do not  
 475 know to what extent the  $N_e / N_c$  ratio might vary from the overall mean for bats (or most other  
 476 organisms). Fourth, the calculation of  $N_e$  using coalescent-based methods requires division of estimates  
 477 of  $\theta$  by the mutation rate ( $\mu$ ) to obtain values of  $N_e$ , but mutation rates are extremely difficult to  
 478 estimate and few good estimates exist for any gene (Ho et al., 2006; Montooth & Rand, 2008; Nabholz,  
 479 Glémin & Galtier, 2009), much less for any bat species. As a result, any inaccuracy in the mutation rate  
 480 estimate is amplified arithmetically in the subsequent calculation of  $N_e$  (Ovenden et al., 2007; Luikart  
 481 et al., 2010). Therefore, applying a standard conversion to convert  $N_e$  to  $N_c$  is highly problematic, and it  
 482 is best to use our estimates to indicate relative orders of magnitude of bat population sizes rather than  
 483 to provide any specific population size estimates.

484         The potential value of our estimates of  $N_e$  is that they may be used as a baseline for future  
 485 monitoring. Assuming fatality rates at wind turbines remain high and continue to grow as wind energy  
 486 development continues, it is possible that regular estimates of  $N_e$  could be utilized to document  
 487 population trends of affected species (Antao, Perez-Figueroa & Luikart, 2011). Regional projections of  
 488 bat fatalities predict annual fatality rates numbering in the tens of thousands (Kunz et al., 2007), and  
 489 the total number of fatalities is likely to continue to rise as wind power development expands.  
 490 However, the loss of genetic variation from populations and declines in  $N_e$  estimates based on linkage  
 491 disequilibrium are only apparent when population sizes are very small (e.g., Waples & Do, 2010),  
 492 suggesting that cumulative population declines may have to be very severe before they affect genetic  
 493 estimates. Had our estimates of  $N_e$  been considerably smaller, or had we detected numerous  
 494 subpopulations among which gene flow was restricted, then there may have been greater potential to

document population size changes using genetic approaches. Given our results supporting a large, panmictic population, simulation studies are required to assess the sensitivity of coalescent-based estimates of  $N_e$  to population decline and to assess the utility of this approach for eastern red bats.

Our genetic data indicating panmixia and a lack of evidence for the use of different migratory pathways in different parts of the range highlights the need to consider the global implications of current and future fatalities associated with wind power. Despite growing conservation concern, current monitoring of bat fatalities at wind power developments is performed on an ad-hoc, site-by-site basis and may vary tremendously in scope according to local regulations. While such monitoring can provide valuable insights leading to site-level mitigation strategies or changes in turbine placement in some cases, biologists lack the necessary broader context within which to assess the long term, population-level impacts of observed fatality rates and management strategies at specific sites. For instance, site-specific, per-turbine thresholds to limit fatalities through curtailment (reducing turbine blade speed and operating time on low-wind nights in summer and fall to decrease fatalities; Baerwald et al., 2009; Arnett et al., 2011) ignore the fact that the demographic consequences of mortality extend well beyond any particular jurisdiction. Evidence from stable isotopes indicates that bats killed at wind power developments may originate from wide geographic areas (Voigt et al., 2012; Baerwald et al., 2014), and thus mortality at any given site can impact bat populations using geographically widespread catchment areas. Given that observed bat fatality rates at wind power facilities vary considerably among sites and regions (Arnett et al., 2008), our findings underscore the need for better data integration across jurisdictions and monitoring programs to adequately assess the cumulative demographic and genetic impacts of continued fatalities.

## ACKNOWLEDGEMENTS

# **Table 1**(on next page)

Sites sampled and diversity statistics for 16-locus microsatellite genotypes and mitochondrial HV2 sequences.

Site labels represent two-letter state codes as in Figure 1.  $N_{Gen}$  = number of individuals genotyped,  $N_A$  = number of alleles,  $H_o$  = observed heterozygosity,  $H_E$  = expected heterozygosity,  $AR$  = allelic richness,  $AR_{Priv}$  = private allelic richness,  $F_{IS}$  = inbreeding coefficient,  $N_{Seq}$  = number of individuals sequenced at mitochondrial HV2 locus,  $N_H$  = number of haplotypes,  $h$  = haplotype diversity,  $\pi$  = nucleotide diversity. Overall values represent means for all measures except  $N_{Gen}$  and  $N_{Seq}$ , which represent sums.

1

Figure 1. Map showing the range of eastern red bats and all sampling locations

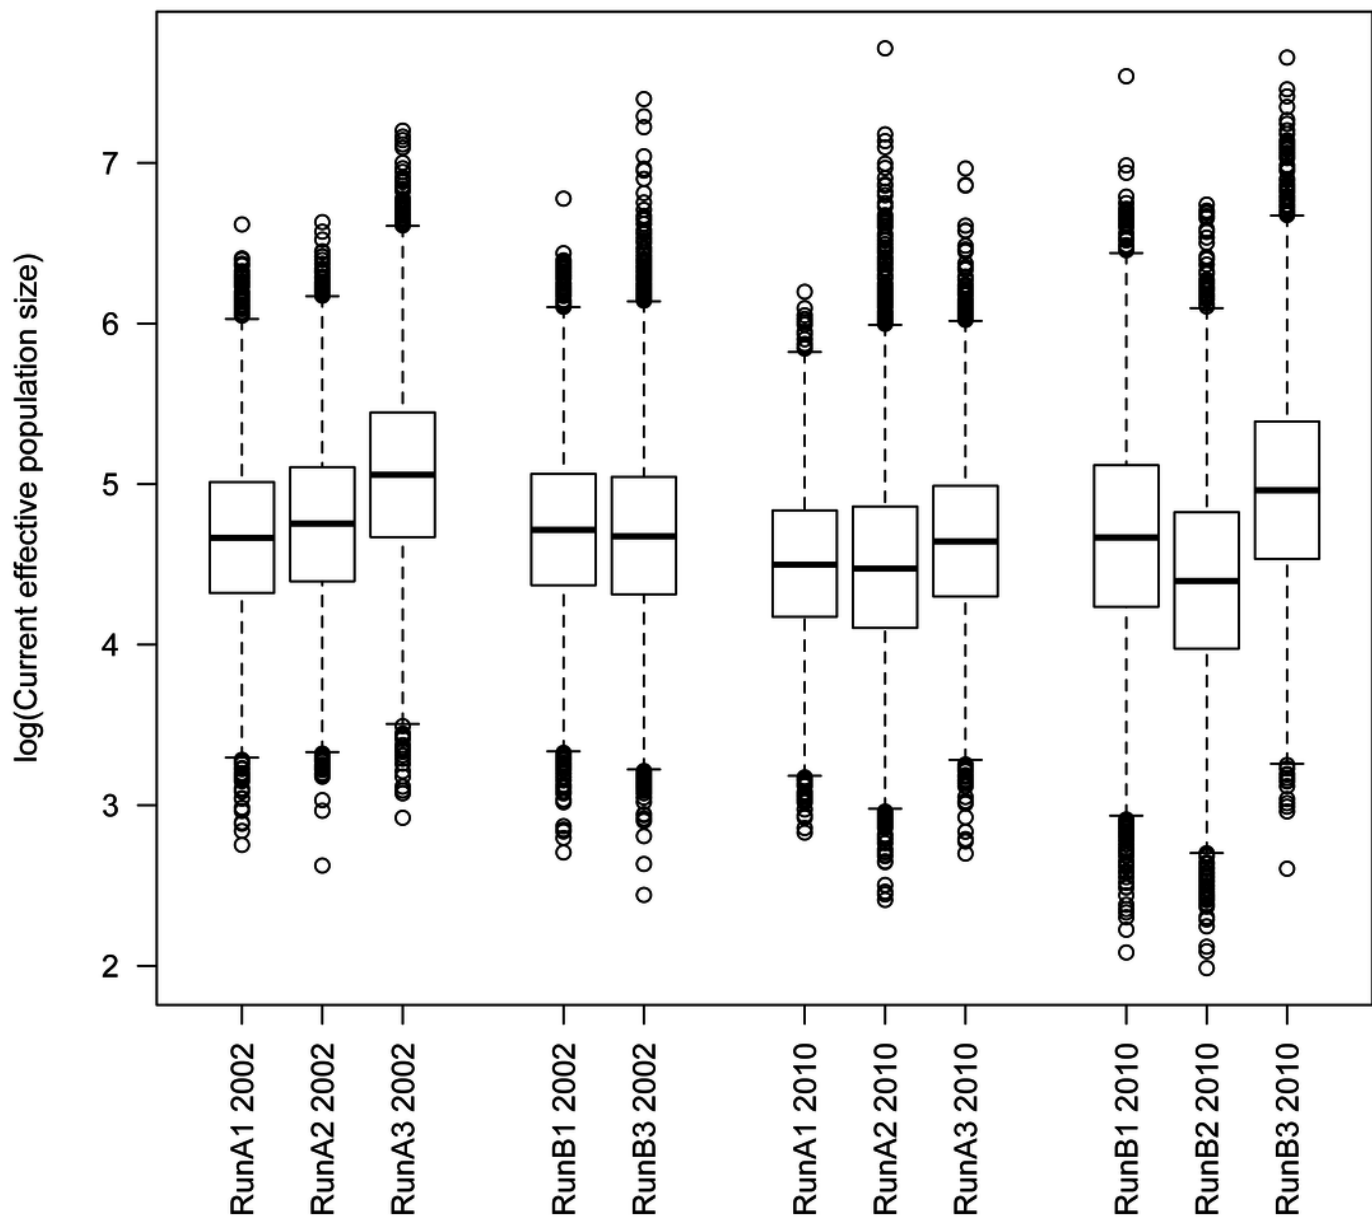

Only labeled locations (black dots) had sufficient sample sizes to be included in population-level analyses, and labels reflect two-letter state or province codes (two sampling locations within West Virginia are further labeled with the first two letters of the county to distinguish them). The range map source is the IUCN (<http://www.iucnredlist.org/details/11347/0>).

2

Tukey boxplot of current  $N_e$  from msvar analyses.

Estimates are given on the  $\log_{10}$  scale. Datasets A and B represent different subsamples of the full dataset from each respective year.

### 3

Posterior probability of  $N_e$  for eastern red bats, estimated using IMA2.

The analysis includes autosomal DNA sequence data, mitochondrial DNA sequence data, and autosomal microsatellite genotype data.
