Cannibalism is considered one of the causes of intra-cohort size divergence in fish and is usually believed to result in increased fitness in terms of survival and reproduction, but direct evidence of this is lacking. Population demographics of the clearhead icefish (*Protosalanx chinensis*) from Lake Xingkai (Khanka) were investigated for one year. Size-frequencies exhibited a bimodal distribution from July through January, where the population diverged into an upper and a lower modal group based on size. Stomach content analysis confirmed the occurrence of cannibalism, where fish belonging to the larger, upper modal group preyed upon those of the smaller, lower modal group. We found *P. chinensis* does not spawn until all of the oocytes have reached maturity and then a single spawning event occurs although the oocytes may develop asynchronously in the ovary. Upper modal group females matured slightly earlier than those of the lower modal group, and reproductive investment was considerably greater in the upper modal group than the lower modal group. The lower modal males made up the majority of the population after the spawning period, which meant they may have few opportunities to participate in reproduction. Therefore, piscivory and cannibalism of *P. chinensis* appears to have increased fitness of the fish belonging to the upper modal group and reduced the fitness of those belonging to the lower modal group greatly.

23 **Abstract**

24 Cannibalism is considered one of the causes of intra-cohort size divergence in fish and is usually  
25 believed to result in increased fitness in terms of survival and reproduction, but direct evidence  
26 of this is lacking. Population demographics of the clearhead icefish (*Protosalanx chinensis*) from  
27 Lake Xingkai (Khanka) were investigated for one year. Size-frequencies exhibited a bimodal  
28 distribution from July through January, where the population diverged into an upper and a lower  
29 modal group based on size. Stomach content analysis confirmed the occurrence of cannibalism,  
30 where fish belonging to the larger, upper modal group preyed upon those of the smaller, lower  
31 modal group. We found *P. chinensis* does not spawn until all of the oocytes have reached  
32 maturity and then a single spawning event occurs although the oocytes may develop  
33 asynchronously in the ovary. Upper modal group females matured slightly earlier than those of  
34 the lower modal group, and reproductive investment was considerably greater in the upper modal  
35 group than the lower modal group. The lower modal males made up the majority of the  
36 population after the spawning period, which meant they may have few opportunities to  
37 participate in reproduction. Therefore, piscivory and cannibalism of *P. chinensis* appears to have  
38 increased fitness of the fish belonging to the upper modal group and reduced the fitness of those  
39 belonging to the lower modal group greatly.

40

41

## 43 Introduction

44 Many piscivorous fishes exhibit an ontogenetic dietary shift, transitioning from non-fish  
45 prey to piscivory over time. An early transition to piscivory is thought to result in increased  
46 growth and reproductive fitness, decreased mortality, and therefore enhanced lifetime fitness  
47 (Werner and Gilliam 1984; Post et al. 1988). In some piscivorous fishes, young-of-the-year  
48 (YOY) intra-cohort individuals exhibited differential timing to the onset of piscivory, driving  
49 bimodal size frequency distributions and cannibalism in the age-0 group. In these cases, the  
50 larger, upper modal group (cannibals) increased their growth rate and decreased survival rate of  
51 the smaller, lower modal group (prey) (Buijse and Houthuijzen 1992; Frankiewicz et al. 1996;  
52 Post 2003; Huss et al. 2010; Heermann et al. 2013). However, direct evidence of increased  
53 reproductive fitness with the transition to piscivory is absent, although Post (2003) suggested that  
54 an early transition to piscivory may result in higher lifetime fecundity since these fish have a  
55 larger relative size and potentially more spawning opportunities in a lifetime.

56 The clearhead icefish, *Protosalanx chinensis* (Abbott 1901), is a small, pelagic, euryhaline  
57 fish species of the family Salangidae that occurs in eastern Asia (Xie and Xie 1997; Saruwatari et  
58 al. 2002). It is a short-lived semelparous fish, completing its lifecycle in about 1 year (Tang et al.  
59 2012). Early-stage juveniles feed mainly on zooplankton, while larger individuals in young and  
60 adult-stage could switch to fish and shrimp and feed primarily on conspecifics (Tang et al. 2013).  
61 The size-frequency of the population becomes bimodal from Month to Month (Zhu 1985).  
62 Considering the unique biological characteristics of *P. chinensis*, we present evidence of within-  
63 population size divergence, and the advantage of larger individuals over smaller individuals in

64 survival and reproduction. These findings provide direct evidence of cannibalism, and its effects  
65 on reproductive fitness of both females and males.

66

## 67 **Methods**

### 68 Study area

69 Lake Xingkai (Khanka) is a large shallow lake, located between China and Russia, serving  
70 as a boundary. It is connected to the Ussuri River through the Sungacha River. The northern part  
71 of the lake (28% of the total area) is located in China and the southern part (72% of the total  
72 area) is located in Russia. The water level area in Khanka is variable and varies from 3940 to  
73 5010 km<sup>2</sup>. The long-term average water level area is 4070 km<sup>2</sup> with an average depth of 4.5 m.  
74 Since 2010, there has been an increase in the water level in the lake. Lake Khanka/Xingkai is one  
75 of the most important international wetlands in the world. Specimens were sampled from the  
76 northwestern part of Khanka Lake near the locality of Dangbi in China(N 45° 15' 49.12" -  
77 45° 15' 8.62" , E 132° 02' 35.22" - 132° 01' 7.73" , Fig.1).

78

### 79 Sampling procedure

80 Clearhead icefish (*P. chinensis*) were sampled monthly from March 2010 through March  
81 2011 except for April 2010. Different sampling gear was used in winter and ice-free seasons to  
82 sample fish effectively. A cone trawler net (length, 3 m; diameter, 1 m; mesh size, 1 x 1 mm)  
83 was used for sampling fish in May, while a seine net (length, 200 m; height, 8 m; mesh size, 2 x  
84 2 mm) was used for sampling from June through November 2010. For each sample, the seine net

85 was drawn parallel to the shore where the water depth was less than 1.5 m, for about 50 m.  
86 Further, four gill nets (length, 30 m; height, 1 m; mesh size, 10 mm, 15 mm, 20 mm, and 23 mm  
87 between opposite knots) positioned randomly were deployed in gangs, tied end to end  
88 perpendicular to the shore for 24 h per month during the freeze-up period (March 2010 and  
89 December 2010 to March 2011). For the reproductive biology and cannibalism experiments, we  
90 used two extra gill nets (length, 100 m; height, 1 m; mesh sizes, 20 and 23 mm between opposite  
91 knots) in the freeze-up period to obtain adequate samples.

92

93 Life history traits analysis

94 The clearhead icefish died immediately after they were captured in nets. Over 100 specimens  
95 were caught in each monthly sample and were measured for standard length (SL; to the nearest 1  
96 mm) and weight (WB; to the nearest 0.01 g). A row of scales typically appears at the base of the  
97 anal fin of maturing males and the anal fin also becomes larger and wave-shaped in mid-October,  
98 but no sexual dimorphism appears before that point, so the sex of each fish was determined by  
99 examining dissected gonads. Females have a larger ovary on the left of the ventral cavity and a  
100 smaller ovary on the right side, while males have a single testis on the right of the cavity. Sex  
101 ratios were determined, and their difference from parity was tested using a binomial test. Chi-  
102 square tests were performed to assess differences in sex ratios among months.

103 The gonads of females sampled in November, December, and January were used to  
104 determine the gonadosomatic index (GSI) and maturity stage, and more than 50 specimens were  
105 dissected for reproductive biology studies each month. In *P. chinensis*, the left ovary is usually

106 larger than the right one. The middle portion of the left ovary was selected for histological  
 107 examination. Stages of maturity were classified into six phases according to Sun (1985). Both  
 108 ovaries were removed and weighed to the nearest 0.0001 g ( $W_G$ ), and the GSI was calculated as  
 109 follows:

$$110 \text{ GSI} = 100W_G / (W_B - W_G).$$

111 The number of oocytes (both pre-vitellogenic and vitellogenic oocytes) from dissected  
 112 ovaries was counted in December and January. Two sub-samples of tissue weighing  
 113 approximately 0.1 g were taken from the middle section of each ovary and preserved in 5%  
 114 formalin. The oocyte counts in these two sub-samples were determined using a dissecting  
 115 microscope and were used to estimate fecundity if the coefficient of variation of N per unit ovary  
 116 weight was below 5% for the two sub-samples. The total fecundity ( $F_A$ ) and relative fecundity  
 117 ( $F_R$ ) were calculated in January as follows:

$$118 F_A = \sum C_n W_{On} / W_{Sn} \text{ and } F_R = 100 F_A / W_B,$$

119 where  $C_n$  is the counted number of eggs in sub-sample n,  $W_{On}$  is the corresponding ovary  
 120 weight,  $W_{Sn}$  is the sub-sample weight and n is the number of subsamples.

121 To reveal the proportion of pre-vitellogenic oocyte change with overall gonad development,  
 122 the most advanced oocyte diameters were determined by measuring the 10 largest oocytes under  
 123 a dissecting microscope to represent the advancement of gonad development (West 1990). The  
 124 proportion of pre-vitellogenic oocytes ( $P_p$ ) can be described as:

$$125 P_p = 100(N_p \times N - 1)$$

126 The Mann-Whitney U test was used to compare the developmental stages of gonads between the

127 upper and lower modal groups in the same cohort within the maturing season. The difference in  
128 GSI between November, December, and January, as well as the difference in fecundity between  
129 December and January, was tested using analysis of covariance (ANCOVA) with WB as the  
130 covariate. Differences in GSI, fecundity, and relative fecundity between the upper and lower  
131 modal groups in January were examined using one-way analysis of variance (ANOVA). The  
132 difference of Pp between December and January was compared using Mann-whitney U test. The  
133 relationship between Pp and the most advanced oocyte diameters was analyzed with general  
134 linear models. All statistical analyses were conducted using STATISTICA 12.0 (StatSoft, Tulsa,  
135 OK, USA).  $P < 0.05$  was considered significant.

136

137 Analysis of cannibalism

138 *P. chinensis* are translucent, allowing for gross examination of gut contents and visual  
139 identification of cannibalism in individuals. We chose to dissect cannibals with visible prey in  
140 their guts. Cannibals and prey were examined for SL (to the nearest 1 mm). The prey to cannibal  
141 size ratios in about 20 cases were calculated for each month from July through December.

142

## 143 Results

144 Growth and intra-cohort size divergence

145 Two cohorts of *P. chinensis* were identified during the sampling period. Individuals  
146 collected in March 2010 belonged to the 2009 cohort and the individuals sampled after March  
147 2010 belonged to the 2010 cohort. Samples collected in March 2010 ranged in SL from 81 to 225

148 mm and consisted of reproductive females and males from the 2009 cohort. *P. chinensis*  
149 juveniles belonging to the 2010 cohort were sampled from May 2010 onwards, and the SL  
150 distribution pattern was unimodal until early July, when a bimodal length distribution began to  
151 emerge and lasted through January 2011. From November to January, the reproductive  
152 population could be divided into the lower modal group (SL < 120 mm) and upper modal group  
153 (SL > 120 mm) on the basis of size (Fig. 2). The population sampled in February and March did  
154 not exhibit a bimodal distribution because the fish died after spawning.

155

#### 156 Characteristics of cannibals and prey

157 Cannibalism was first observed in July. The SL of cannibals sampled during this month  
158 ranged from 65 to 91 mm, while those of prey ranged from 38 to 52 mm. Both cannibals and  
159 prey grew larger over time. The cannibals generally reached a SL of >120 mm by November,  
160 and the prey were usually smaller than 120 mm (Table 1). Given that the reproductive population  
161 in November could be divided into two size groups by SL with 120 mm as the cutoff (Fig. 2), it  
162 is apparent that the upper modal group was comprised of cannibals and the lower modal group  
163 was comprised of the prey. The prey to cannibal size ratio ranged from 0.47 to 0.67 (Table 1).

164

#### 165 Examination of sex ratio

166 The sex of all sampled individuals was determined from early October 2010 to early March  
167 2011. Monthly observations of sex ratios (male to female) did not differ from parity (1:1) from  
168 October through January ( $P = 0.808, 0.410, 0.563, 0.621$ , respectively) or vary significantly

169 among months ( $x^2 = 1.499$ ,  $df = 3$ ,  $P = 0.683$ ). However, the sex ratios in February and March  
170 were 13.4 and 18.1, respectively, due to natural mortality of females after spawning (Fig. 3). The  
171 remaining population mainly consisted of males in the lower modal group (Fig. 2). From October  
172 through January, sex ratios did not differ from parity in the upper modal group ( $P = 0.453$ ,  $0.450$ ,  
173  $0.475$ ,  $0.527$ , respectively) or the lower modal group ( $P = 0.462$ ,  $0.409$ ,  $0.428$ ,  $0.635$ ,  
174 respectively).

175

176 Gonad development and the differences between the two groups

177 Oocytes developed asynchronously in ovaries of *P. chinensis*; pre-vitellogenic (Phase III  
178 & II) oocytes and vitellogenic (Phase IV & V) oocytes existed in the same ovary. The gonads of  
179 female *P. chinensis* did not develop to stage II until early October, after which they developed  
180 quickly to stage III in the first half of October. In early November, individuals in stages III and  
181 IV of gonadal development accounted for 61.5% and 38.5% of the female population,  
182 respectively. A few oocytes developed to stage V at the beginning of December, but all the  
183 oocytes in an ovary did not develop synchronously to the same stage. Most female gonads  
184 developed to stage IV or V and the fish could spawn in early January, but only a few post-  
185 spawning individuals were sampled in February and March (Fig. 4). The oocytes developed  
186 asynchronously, and oocytes of different developing phases may commonly occur in the same  
187 ovary of maturing females (Fig.5).

188 The Pre-vitellogenic oocytes occurred in samples from December and January (100%,  $n=50$ )

189 and 22%,  $n=59$ , respectively). The proportion of pre-vitellogenic oocytes ( $P_p$ ) in gonads sampled  
190 in January became significantly lower compared to those sampled in December ( $Z=-15.99$ ,  
191  $P<0.001$ , see Fig. 6). Linear regression indicated that the proportion of pre-vitellogenic oocytes  
192 declined significantly ( $F_{1,107} = 6.18$ ,  $P=0.014$ , see Fig. 6), as indicated by the observation of  
193 increased oocyte diameters in the developing gonads. This indicates that *P. chinensis* will spawn  
194 as many eggs as possible in a single spawning event occurs.

195 Most female gonads developed to stage III or IV in early November, and females in the  
196 upper modal group seemed to mature faster than those in the lower modal group, although this  
197 difference was not significant ( $Z = -1.117$ ,  $P = 0.239$ ). In early December, females in maturity  
198 stage IV accounted for the largest proportion both in the upper (88.5%) and lower modal groups  
199 (81.5%), and the maturity stage distribution was not significantly different between the groups ( $Z$   
200  $= -1.401$ ,  $P = 0.161$ ). In early January, almost all of the female gonads developed to stage IV or  
201 V, and no significant differences were observed in the developmental rates between the groups  
202 ( $Z = -1.934$ ,  $P = 0.053$ ) (Fig. 7).

203

204 Differences in reproductive investment between the groups

205 The GSI increased dramatically from November to January, ranging from 1.8 to 10.2% in  
206 November, 2.9 to 44.1% in December, and 7.6 to 76.4% in January (Fig. 8). Results of the  
207 ANCOVA (BW as the covariate) indicated that the differences in GSI among the three months  
208 were all significant ( $F_{2,161} = 185.3$ ,  $P < 0.001$ ). The GSI of fish in the upper modal group was  
209 significantly higher than that of fish in the lower modal group in November (ANOVA,  $F_{1,50} =$

210 56.3,  $P < 0.001$ ), December (ANOVA,  $F_{1,51} = 50.0$ ,  $P < 0.001$ ), and January (ANOVA,  $F_{1,57} =$   
211 95.1,  $P < 0.001$ ) (Fig. 8).

212 Results of the ANCOVA (BW as the covariate) also revealed no significant difference in  
213 fecundity between early December and early January ( $F_{2,110} = 3.4$ ,  $P = 0.067$ ). In other words,  
214 there was no down-regulation of fecundity during gonad development or indeterminate  
215 spawning. Samples from January were used to analyze intra-population divergence of fecundity.  
216 Fecundity ranged from 1,592 to 36,705 eggs, and relative fecundity ranged from 500 to 1,646  
217 eggs per gram BW. The relative and absolute fecundity were significantly higher in females from  
218 the upper modal group than those in the lower modal group (ANOVA,  $F_{1,57} = 121.5$ ,  $P < 0.001$   
219 and ANOVA,  $F_{1,57} = 21.94$ ,  $P < 0.001$ , respectively) (Fig. 9).

220

## 221 **Discussion**

222 Piscivorous, cannibalism and size divergence

223 Size variation among clearhead icefish populations has been previously reported (Zhu 1985;  
224 Wang and Jiang 1992; Tang et al. 2003). Xie et al. (2001) noted two peaks within the size  
225 frequency distribution of a reproductive population. However, this is the first report of within-  
226 cohort bimodal size distribution in *P. chinensis*. Bimodal size distribution is well documented in  
227 iteroparous fishes (Huss et al. 2010; Alejo-Plata et al. 2011), and studies on Percidae species  
228 revealed diet shift contributing to the size divergences in YOY fish, and that the extreme growth  
229 of the upper modal group was induced by piscivory (cannibalism) (Frankiewicz et al. 1996; Post  
230 2003; Urbatzka et al. 2008). The synchronous investigation on diet composition showed that a

231 few bigger individuals of *P. chinensis* began to feed on fish and cannibalism also occurred in  
232 early July, and then piscivory and cannibalism accompanied the size bimodal pattern forming  
233 (Tang et al. 2013). And the victims of cannibalism accounted for the majority of the diet of  
234 cannibals in December and January (Tang et al. 2013).

235

236 Fitness of the cannibals

237 The absolute and relative fecundity reported in the present study for a population of *P.*  
238 *chinensis* in Lake Khanka shows wider range (1,592 - 36,705 eggs, and 500 - 1,646 eggs/gram-  
239 BW) than populations from other locations (3,295 to 34,520 eggs, and 340 to 1,290 eggs/gram-  
240 BW) (Zhang et al. 1981; Xie et al. 2001). While there is no published information illustrating the  
241 difference in reproductive investment between the two modal groups of clearhead icefish, this  
242 investigation demonstrates that the reproductive investment of females belonging to the upper  
243 modal group(cannibals) was significantly higher than that of females from the lower modal  
244 group(victims) in terms of GSI, absolute fecundity and relative fecundity. In common, larger fish  
245 has higher absolute fecundity and lower relative fecundity than the smaller conspecifics. *P.*  
246 *chinensis* cannibals have both higher absolute fecundity and relative fecundity than the victims,  
247 which means piscivory and cannibalism increased reproductive potential greatly. In addition, the  
248 cannibals grow faster and become bigger than the potential victims, which will increase their  
249 survival rate undoubtedly.

250

251 Gonad development and spawning pattern

252 Researchers have offered multiple theories to describe the reproductive strategy of *P.*  
253 *chinensis*. Sun (1985) reasoned that *P. chinensis* spawn twice during their lifetime upon  
254 examination of their gonad histology, but Xu et al. (2000) determined that this species spawns  
255 once before death. Xie et al. (2001) theorized that *P. chinensis* can spawn once or multiple times.  
256 Our research supports the theory that *P. chinensis* exhibits a semelparous reproductive strategy,  
257 although oocytes developed asynchronously in the same gonad. This is different from other  
258 semelparous species such as chum salmon *Oncorhynchus keta* (Crozier et al. 2008). The  
259 asynchronous development of oocytes should be attributed to the relatively rather high fecundity  
260 and the nutrition may not be enough to develop all the oocytes at the same time, which is a  
261 mechanism to produce as many eggs as possible in a spawning event in a life time.

262

263 Sex ratio and mate selectivity

264 Sex ratios did not differ from parity before spawning (October through December) or during  
265 spawning (primarily early to mid-January) in both the upper modal and lower modal groups.  
266 This is similar to reports for this species from other locations (Zhang et al. 1981; Sun and Zhou  
267 1989; Xu et al. 2000; Xie et al. 2001). However, we found that the reproductive population was  
268 mainly composed of males in the lower modal group after January. We hypothesize that males in  
269 the lower modal group have a reduced opportunity to participate in spawning. The intra-cohort  
270 sex selectivity of *P. chinensis* may influence evolution towards early birth and faster growth,  
271 although this theory requires further study.

272

273 Life history strategy

274 The *P. chinensis* is a small fish that matures early with a short life span and relatively high  
275 fecundity. This makes it an exception from the three-point life-history continuum model  
276 proposed by Winemiller and Rose (1992). Larger individuals (upper modal group) tend to exhibit  
277 an opportunistic life-history strategy, but characterized by relatively higher fecundity. An  
278 opportunistic colonization strategy facilitates range expansion of an invading species through  
279 early maturity in frequently changing or stochastic environments (Fox et al. 2007; Ribeiro et al.  
280 2009). Exceptional higher fecundity would undoubtedly contribute to rapid increase in  
281 population size and spread of the opportunistic fish, *P. chinensis*.

## 282 Conclusion

283 Transition to feed on fish increased the investment of the female *P. chinensis* and may also  
284 increase the fitness of male in reproductive competing. This research provided a direct evidence  
285 that transition to be carnivorous is positively significant in evolution, although further study on  
286 increasing the fitness of male *P. chinensis* need to be conducted.

# Figure 1

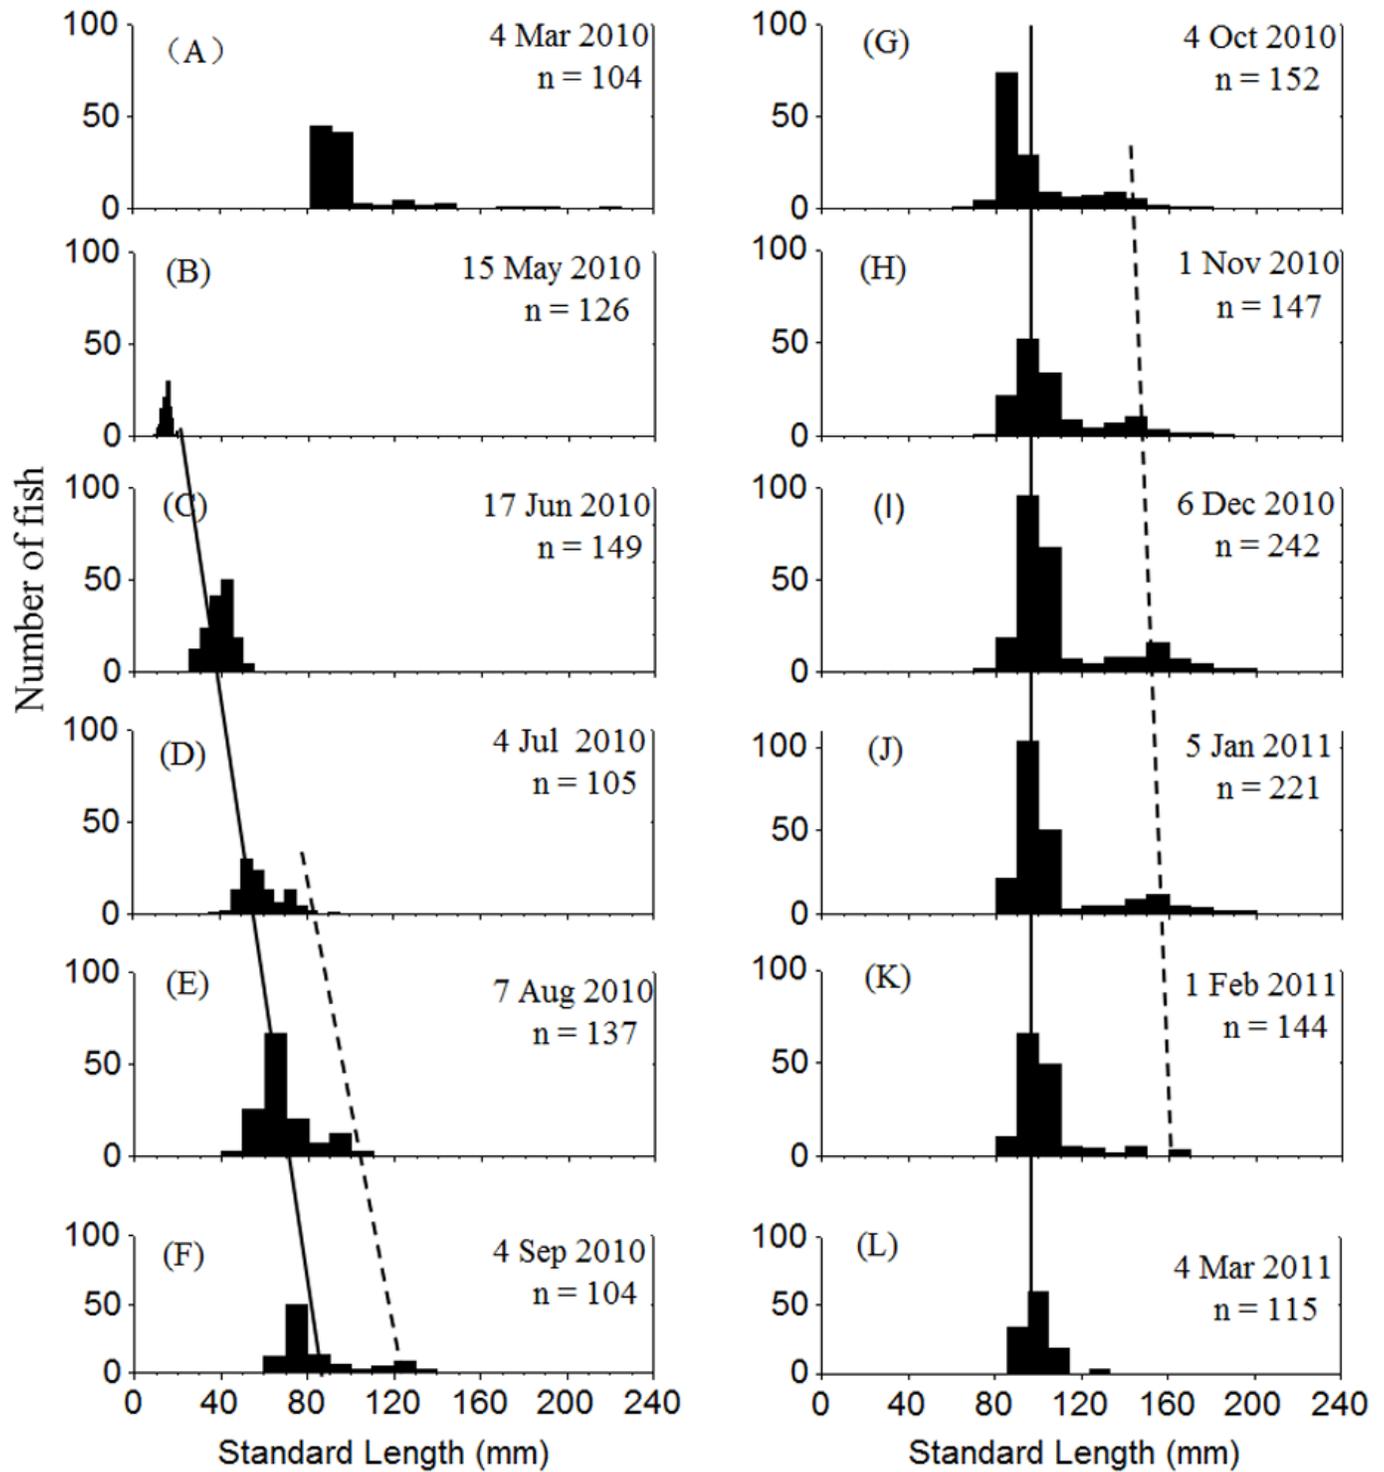

Location of Lake Khanka (China/Russia) and sampling site.

## Figure 2

. Standard length frequency distribution of *P. chinensis* in Lake Khanka from March 2010 through March 2011. The solid line connects lower modal groups and the dashed line connects upper modal groups.

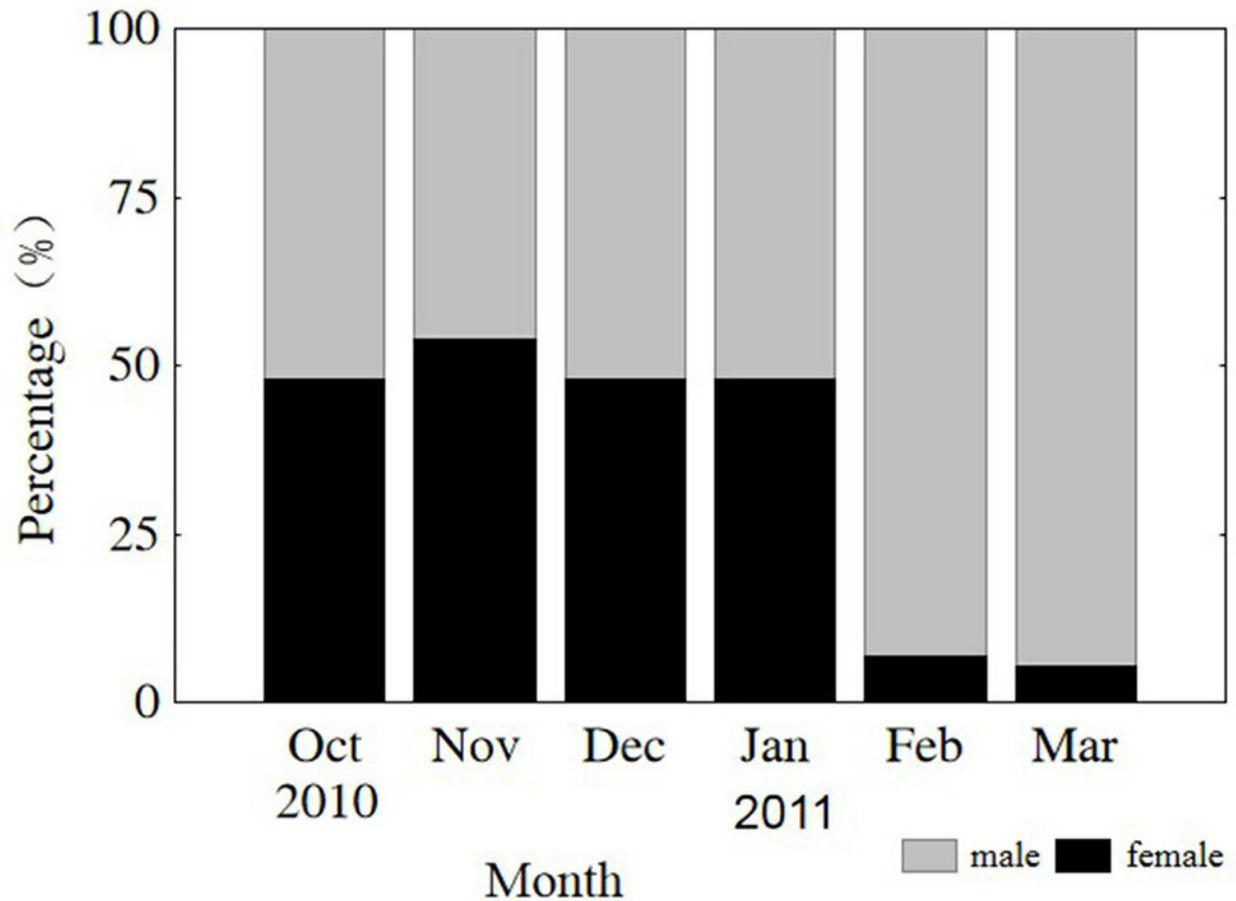

A, Cohort born in 2009; B-L, Cohort born in 2010. Jan, January; Feb, February; Mar, March; Jun, June; Jul, July; Aug, August; Sep, September; Oct, October; Nov, November; Dec, December.

## Figure 3

Monthly sex ratio variation from 4 October 2010 through 4 March 2011.

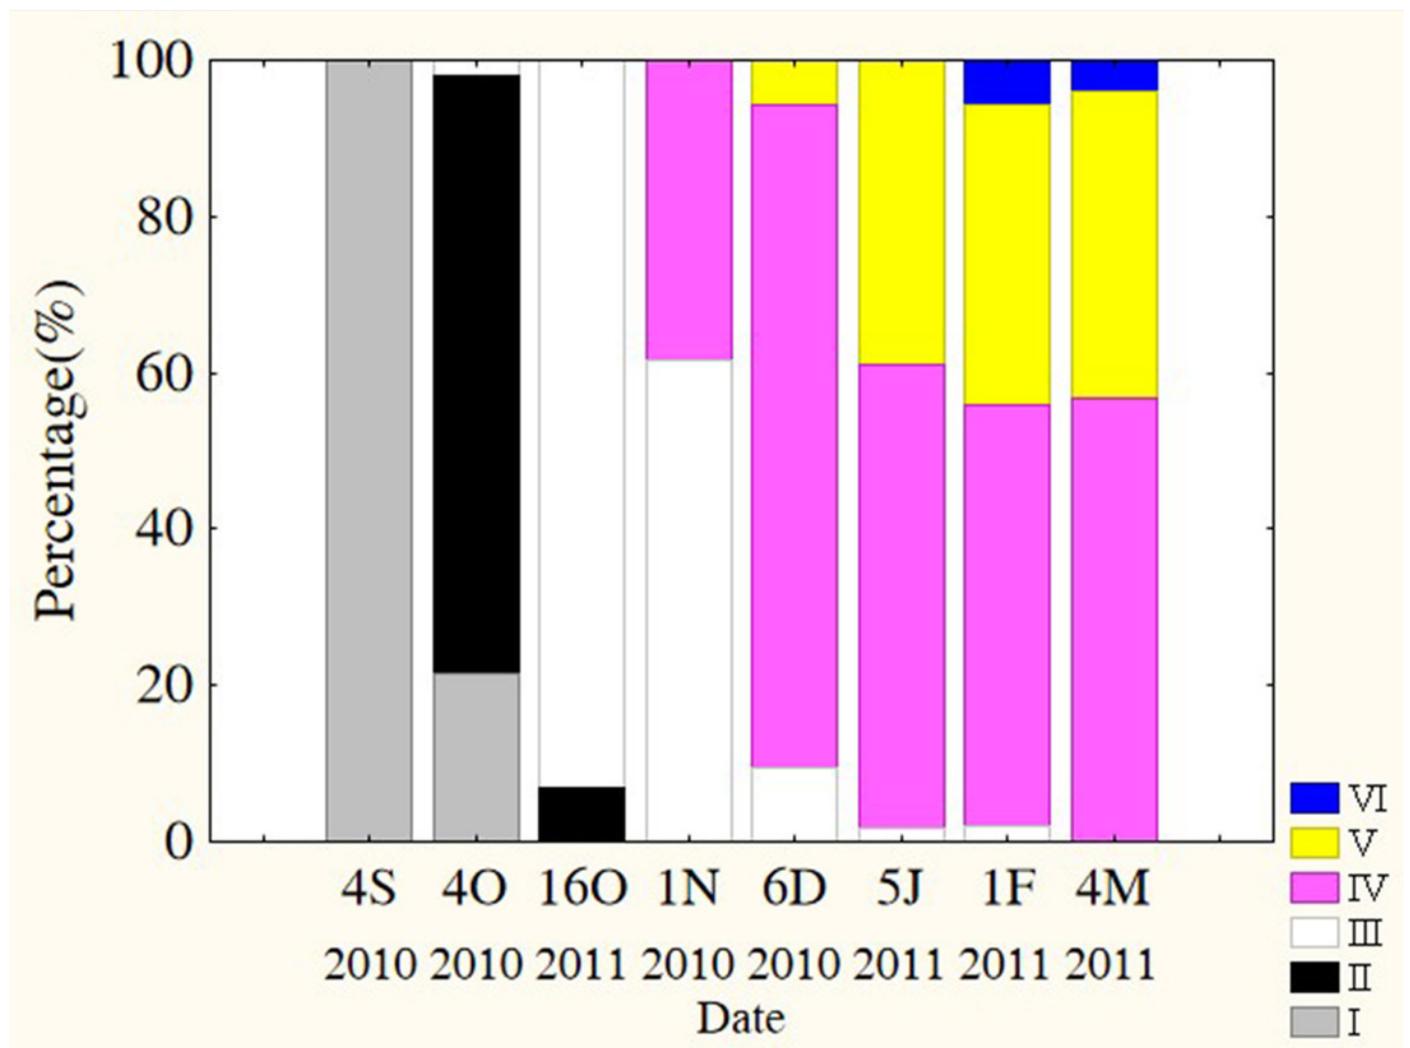

Oct, October; Nov, November; Dec, December; Jan, January; Feb, February; Mar, March.

## Figure 4

Percentage of *P. chinensis* at different ovarian maturity stages from early October through early March.

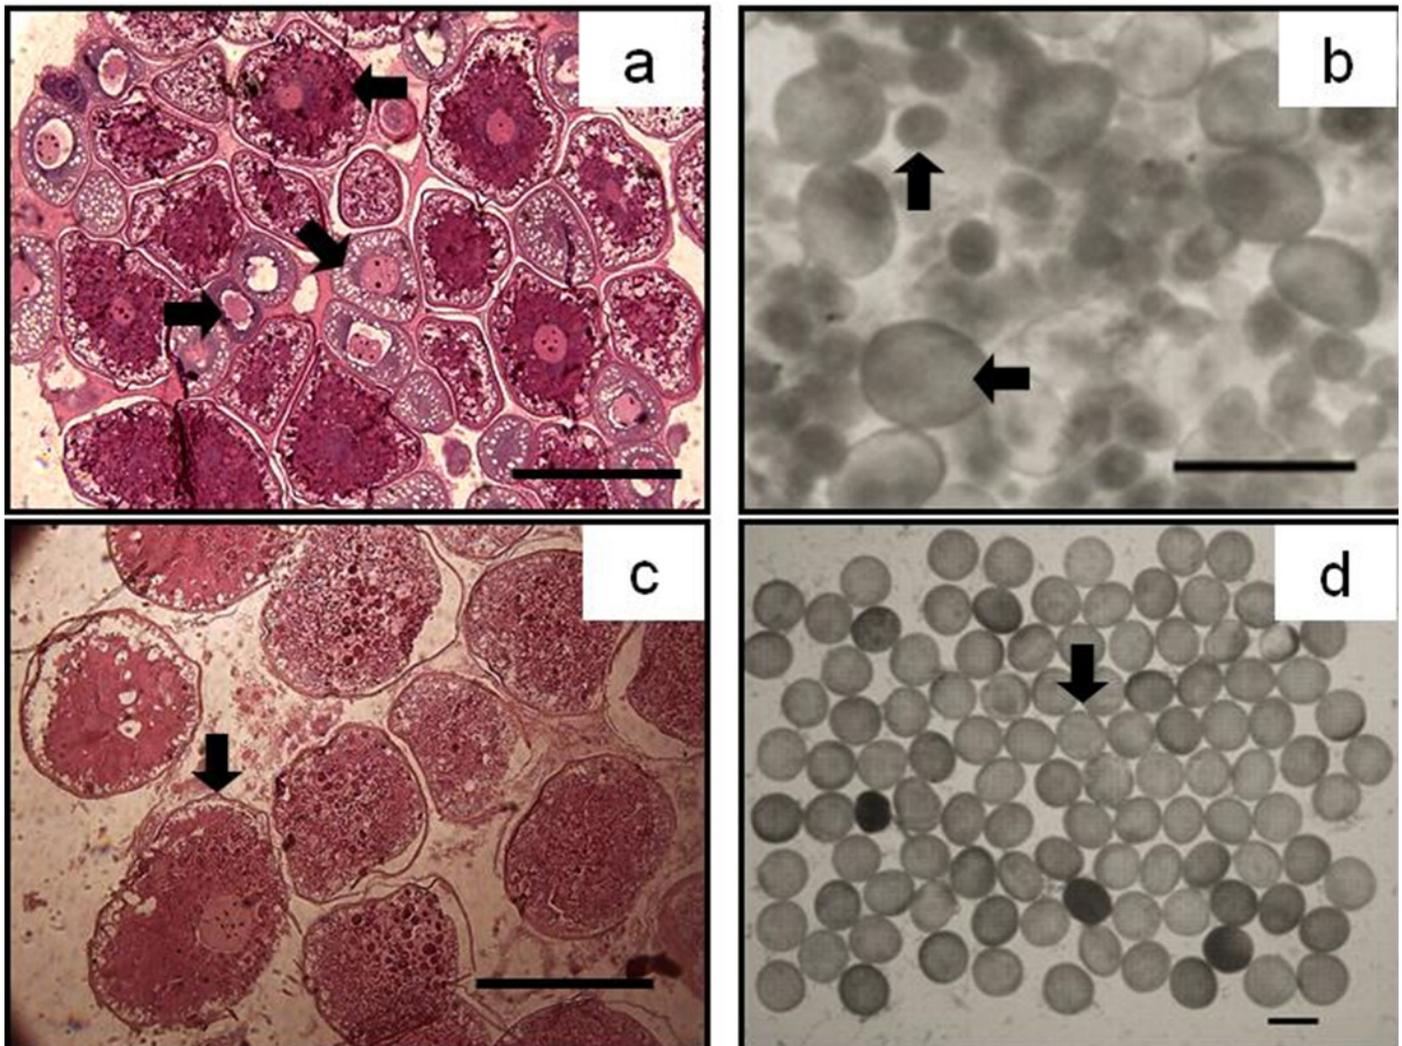

Gonad maturity stage: *white*, I; *crossed*, II; *vertical lines*, III; *horizontal lines*, IV; *diagonal lines*, V; *black*, VI. S, September; O, October; N, November; D, December; J, January; F, February; M, March.

## Figure 5

The asynchrony of oocytes development of *P. chinensis*.

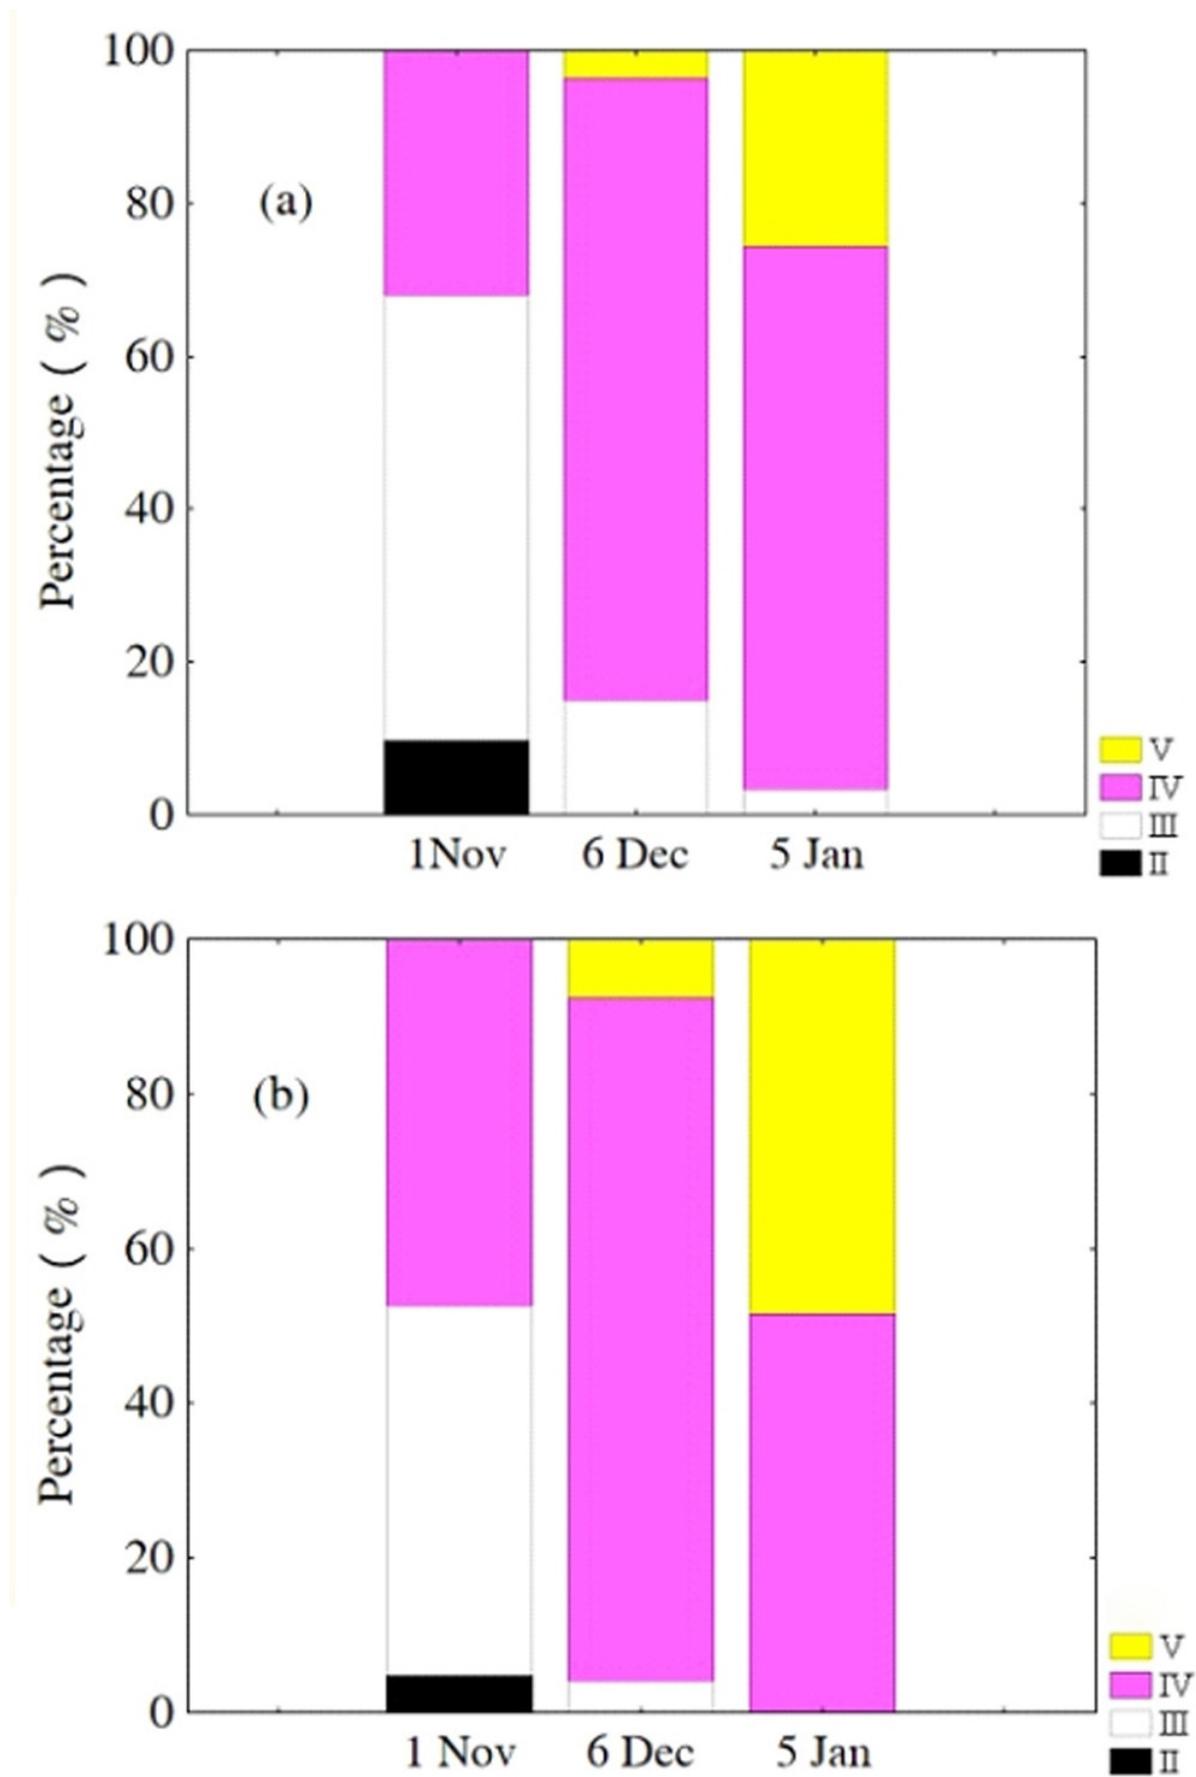

Cross-section of ovary (a) and egg micrograph (b) of a fish in November (SL,145mm; BW,16.64g); cross-section of ovary (c) and egg micrograph (d) of a fish in January (SL,180mm; BW, 26.15g): ( ← ) Phase II (Perinucleolar) oocyte; ( √ ) Phase III (Yolk vesicle) oocyte; ( → ) Phase IV (Yolk) oocyte; ( ↑ ) Pre-vitellogenic (Phase II&III) oocyte; ( ↓ ) Phase V (migratory nucleus) oocyte. Scale bar = 1mm.

## Figure 7

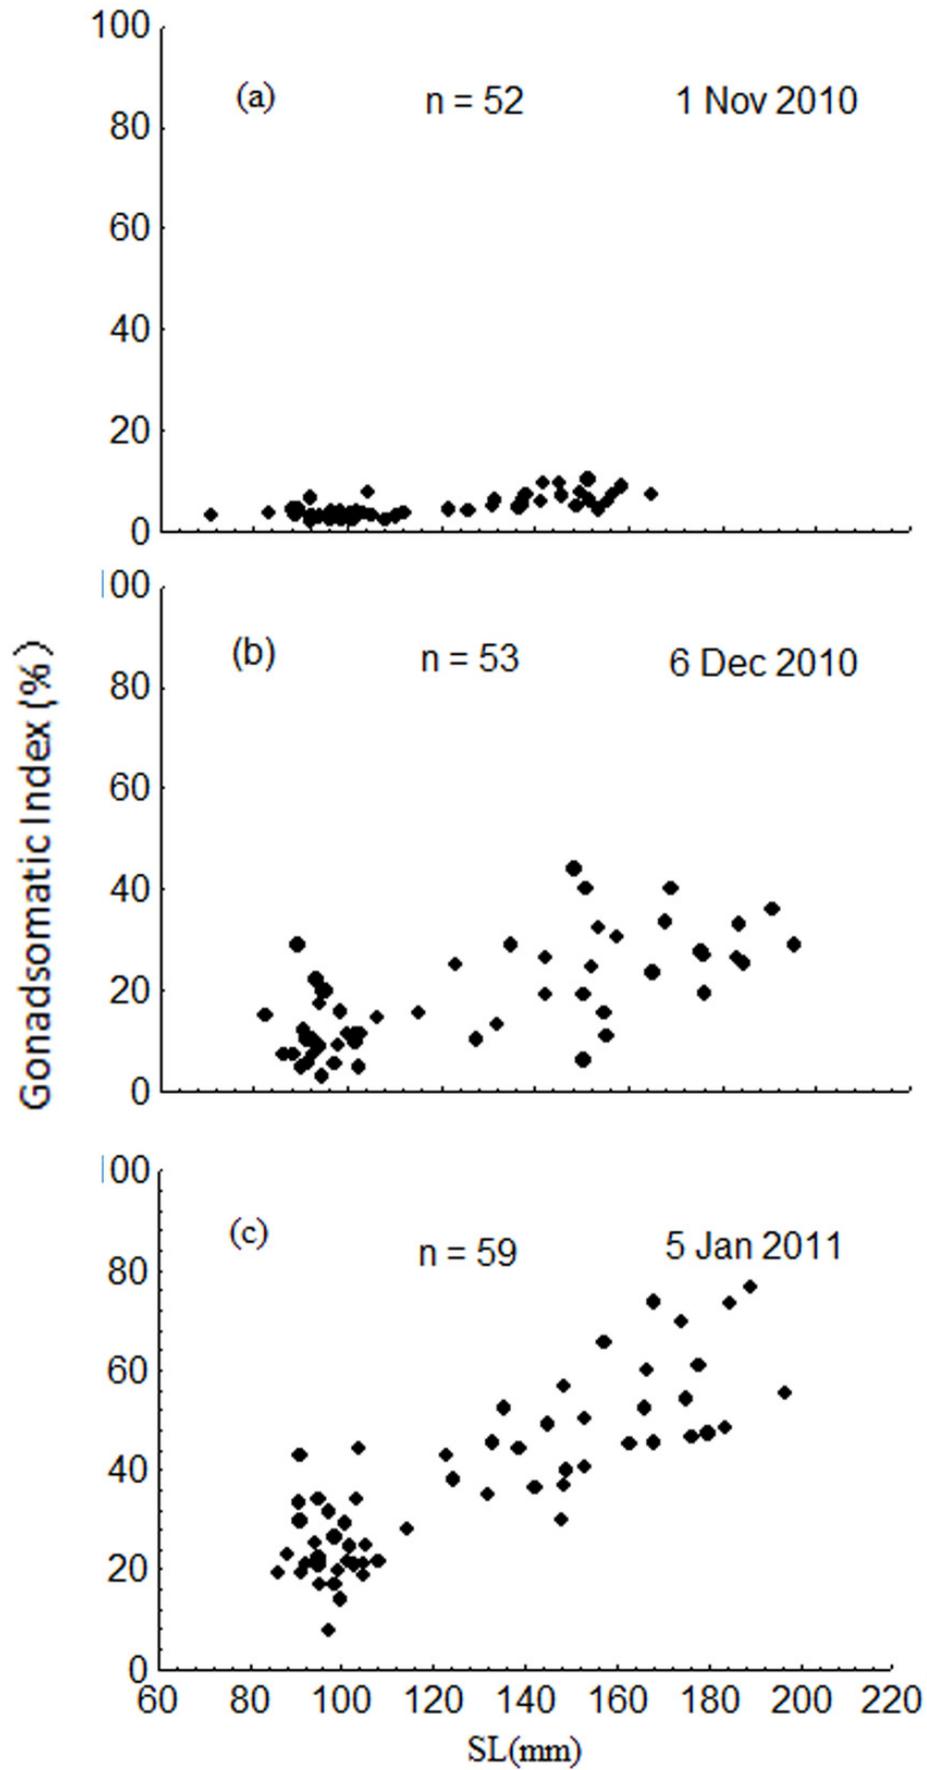

Percentage of *P. chinensis* females with different ovarian maturity stages in early November, December 2010 and January 2011 from the lower modal group (a, SL < 120 mm) and upper modal group (b, SL > 120 mm).

## Figure 8

Intra-population variation in gonadosomatic index (GSI) in November 2010(a), December 2010(b) and January 2011(c).

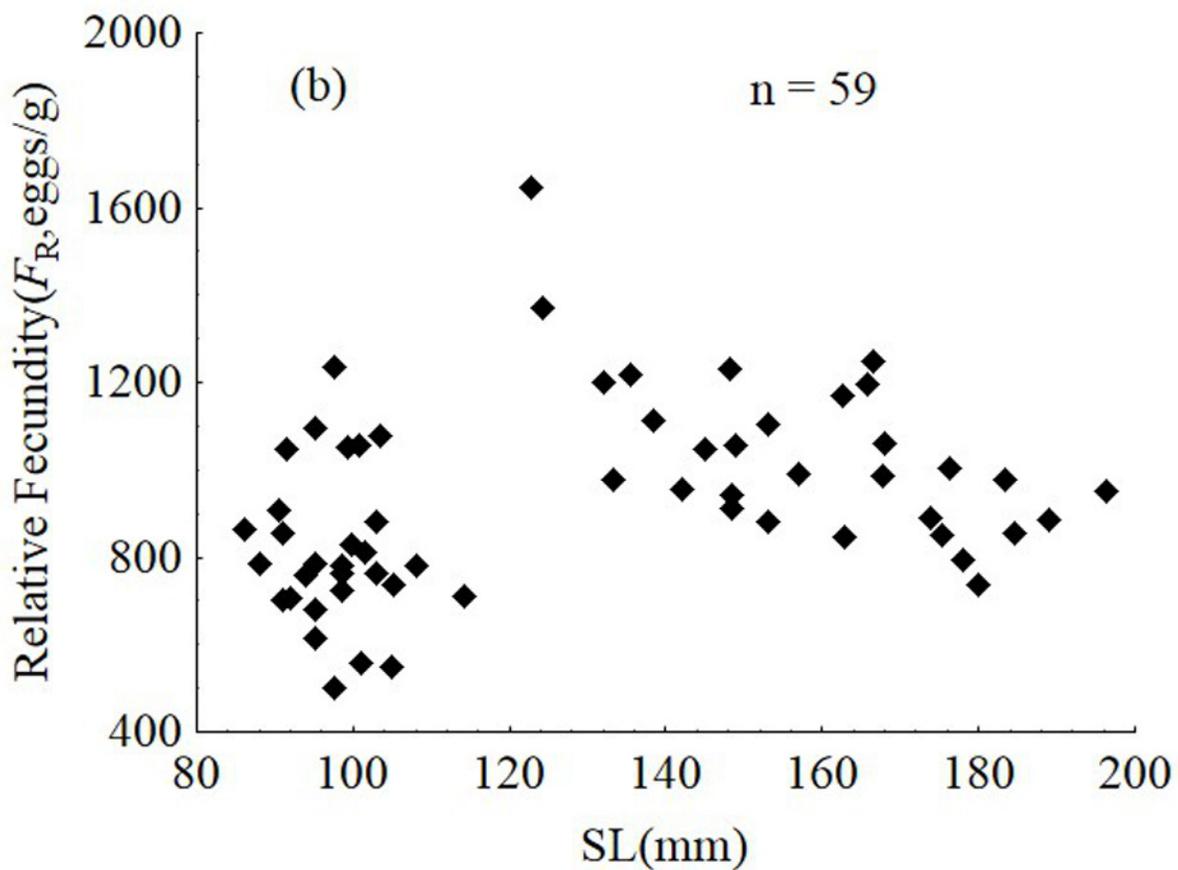

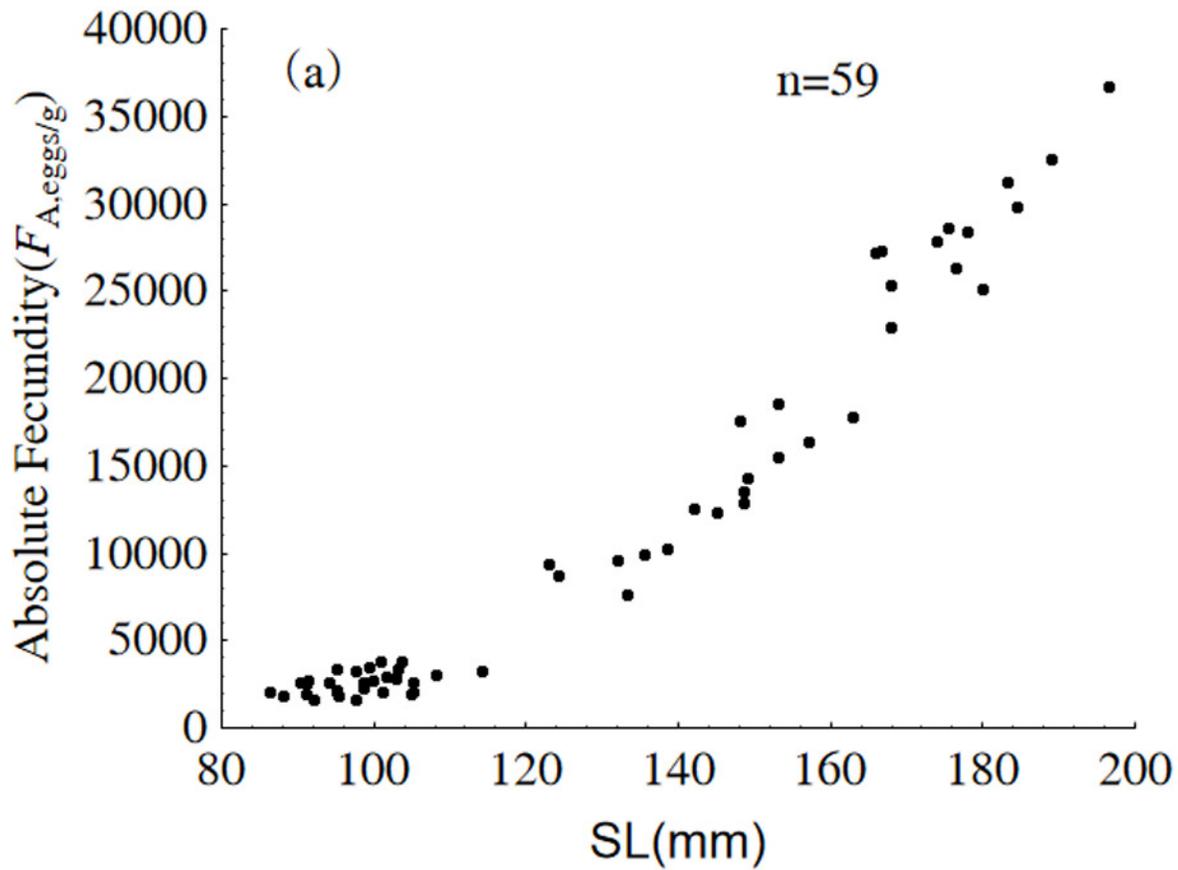

SL = standard length.

## Figure 9

Absolute fecundity(a) and relative fecundity (b) of *P. chinensis* females sampled in January.

SL = standard length

**Table 1** (on next page)

Differences in mean standard lengths (SL)  $\pm$  standard deviation (SD) between *P. chinensis* cannibals and prey.

Jul, July; Aug, August; Sep, September; Oct, October; Nov, November; Dec, December.

1 Placement of Table 1: Page 9

2

Month	N	SL of cannibals (mm)		SL of the prey (mm)		SL of the prey / SL of cannibals	
		Range	Mean (S.D.)	Range	Mean (S.D.)	Range	Mean (S.D.)
Jul	24	65-91	76±7.2	38-52	48±6.2	0.54-0.65	0.63±0.02
Aug	25	72-110	89±13.5	46-59	51±4.9	0.47-0.64	0.57±0.05
Sep	29	108-146	128±9.5	55-75	65±5.5	0.48-0.54	0.51±0.02
Oct	31	119-177	139±16.1	72-102	83±8.6	0.49-0.67	0.60±0.05 <sup>a</sup>
Nov	27	122-189	147±15.7	71-115	88±10.2	0.51-0.65	0.60±0.03
Dec	35	123-196	153±16.7	82-117	93±9.6	0.50-0.70	0.61±0.04
