## Abstract

22  **Background.** This study examined the impact of heterozygous HbE on HbA1c measurements by

23  six commonly used commercial methods. The results were compared with those from a modified

24  isotope-dilution mass spectrometry (IDMS) reference laboratory method on a liquid

25  chromatograph coupled with tandem mass spectrometer (LC-MS/MS).

26  **Methods.**  Twenty-three leftover samples of patients with heterozygous HbE (HbA1c range:

27  5.4%-11.6%), and nineteen samples with normal hemoglobin (HbA1c range: 5.0%-13.7%) were

28  included. The selected commercial methods included the Tina-quant HbA1c Gen. 3 (Roche

29  Diagnostics), Cobas B 101 (Roche Diagnostics), D100 (Bio-Rad Laboratories), Variant II Turbo

30  HbA1c 2.0 (Rio-Rad Laboratories), DCA Vantage (Siemens Healthcare) and HbA1c Advanced

31  (Beckman Coulter Inc.).

32  **Results.**  With the exception of Cobas B 101 and the Variant II Turbo 2.0, the 95% confidence

33  intervals of the Passing-Bablok regression lines between the results from the six commercial

34  methods and the IDMS method overlapped. The latter suggested no statistically significant

35  difference in results and hence no impact on HbA1c result despite the presence of heterozygous

36  HbE. The method of Cobas B 101 gave positive bias at the range of concentrations examined

37  (5.4%-11.6%), while that of Variant II Turbo 2.0 gave positive bias at concentrations up to

38  approximately 9.5%. The finding of significant positive bias in the methods of Cobas B 101 and

39    Variant II Turbo 2.0 agrees with the observations of some previous studies, but is contrary to
40    manufacturer's claim indicating the absence of interference by heterozygous HbE. Our results
41    also clearly showed the impact of heterozygous HbE across a fairly broad measurement range
42    using a laboratory method (the Variant II Turbo 2.0). Laboratory practitioners and clinicians
43    should familiarize themselves with prevailing hemoglobin variants in the population they serve
44    and select the appropriate methods for HbA1c measurement.
45

## Introduction

47    Hemoglobin E (HbE) is a variant hemoglobin caused by a single point mutation, resulting in
48    glutamic acid to lysine substitution at position 26 of the beta chain of the hemoglobin ($\beta$ 26
49    Glu→Lys). The amino acid substitution shifts the overall molecular charge more basic, which
50    can be detected by separative methods, such as electrophoresis and liquid chromatography.
51    Globally, HbE is the second most common hemoglobin variant with a prevalence of up to 40%
52    in certain populations in South and South-East Asia [1].
53    Hemologbin A1c (HbA1c) measurement is recommended for monitoring of long-term glycemic
54    control and treatment titration in patients with diabetes [2]. The measurement of HbA1c can be
55    affected by the presence of hemoglobin variants, leading to spurious measurement that can
56    adversely affect clinical decision making. This study examined the impact of heterozygous HbE
57    on HbA1c measurements using six commonly used commercial methods and a modified isotope-
58    dilution mass spectrometry (IDMS) reference method [3].
59

## Materials & Methods

61    **Study subjects.**Twenty-three de-identified leftover whole blood samples from patients who had
62    heterozygous HbE (AE) identified by capillary zone electrophoresis (Capillarys Hemoglobin,
63    Sebia, Cedex, France) and gel electrophoresis (Hydragel Hemoglobin, Sebia, Cedex, France)
64    were included in this study (HbA1c range: 5.4% - 11.6%, determined by IDMS). Another twenty
65    de-identified whole blood samples belonging to patients with normal hemoglobin were included
66    as controls (HbA1c range: 5.0% - 13.7%, determined by IDMS).
67

68    **Ethics declaration.**This study was performed as part of the laboratory quality assurance system.
69    The study protocol complies with local regulatory requirements and the Declaration of Helsinki.
70    It has been approved by the institutional ethics review board (National Healthcare Group
71    Domain Specific Review Board, Ref: 2016/01201) with an exemption for written consent for the
72    use of de-identified leftover samples for this study.
73

74    **Laboratory analysis.**The blood samples were subjected to HbA1c measurement using the Tina-
75    quant HbA1c Gen. 3 (immunoassay adapted on Cobas 501 analyser, Roche Diagnostics, Basel,
76    Switzerland), Cobas B 101 (point-of-care immunoassay, Roche Diagnostics), D100 (cation-
77    exchange high performance liquid chromatography (CE-HPLC), Bio-Rad Laboratories,
78    Hercules, CA, USA), Variant II Turbo HbA1c 2.0 (CE-HPLC, Rio-Rad Laboratories), DCA

79    Vantage (point-of-care immunoassay, Siemens Healthcare GmbH, Erlangen, Germany) and
80    HbA1c Advanced (immunoassay adapted on DxC 700 AU, Beckman Coulter Inc., Miami, FL,
81    USA). All the commercial methods had been certified by the National Glycohemoglobin
82    Standardization Program and their details are summarised in Table 1. The blood samples were
83    also subjected to a previously described IDMS reference method [3] using an Agilent 1290
84    Infinity liquid chromatograph coupled with AB SCIEX 6500+ tandem mass spectrometer.
85
86    It has previously been suggested that the glycation rate of HbE is the same as normal hemoglobin
87    (HbA0) since the modification on HbE is far from the site of glycation [4]. The IDMS HbA1c
88    method involved measuring enzymatically digested N-terminal  hexapeptides of the β-chain of
89    the hemoglobin using LC-MS/MS, and does not distinguish between HbE and HbA0. Hence, the
90    IDMS method is unaffected by HbE, and the HbA1c results from this method were considered
91    the reference values in our study. The HbA1c were also separately measured on the six
92    commercial methods. The blood samples were initially analysed by Variant II Turbo 2.0 or
93    Cobas B 101 to ensure that the samples could cover a wide concentration range for this study,
94    then kept at 4°C for less than 7 days before testing on the other commercial methods. The
95    hemolyzed blood samples were stored at -20° for less than two months before testing on the LC-
96    MS/MS.
97
98    **Statistical analysis.**The results for samples with HbE and normal hemoglobin obtained from
99    the methods of the six commercial methods were plotted against those of the IDMS method
100   using Passing-Bablok analysis with 95% confidence intervals obtained by bootstrapping. HbA1c
101   levels of 6% and 9% are clinically important decision values [4]. Hence, the relative difference
102   of HbA1c results between samples with HbE and normal hemoglobin were compared. A relative
103   difference of ±6% were considered significant, as recommended by the College of American
104   Pathologists [5]. The statistical analysis was performed using Analyze-It (Microsoft, Redmount,
105   WA, USA).
106

# Results

108   The Passing-Bablok regression between the results from the routine methods of six selected
109   commercial methods and IDMS method are shown in Figure 1. The regression equations are
110   summarized in Table 2. Except for results from Cobas B 101 and the Variant II Turbo 2.0
111   methods, all the 95% confidence intervals of the regression lines overlapped, suggesting no
112   statistically significant difference in results for the methods of the other four commercial
113   methods. In the presence of heterozygous HbE, the Cobas B 101 method had positive bias at the
114   range of concentrations examined (5.4%-11.6%), while the Variant II Turbo 2.0 method had
115   positive bias at concentrations up to approximately 9.5%.
116
117   The relative difference between heterozygous HbE and normal hemoglobin at HbA1c of 6% and
118   9% are summarized in Table 3. Results from the Cobas B 101 method (difference = +6.4% for

119    HbA1c at 6%; difference = +7.4% for HbA1c at 9%) and the Variant II Turbo 2.0 method
120    (difference = +9.9% for HbA1c at 6%) exceeded the a priori criteria for significance. The
121    relative difference at 9% for the Variant II Turbo 2.0 method was +4.4%, which was within the a
122    priori criteria for significance.
123

## Discussion

125    The six commercial methods examined in this study included commonly used mainframe
126    analyzer and point-of-care systems. Together, they represented the methods used by 36% of the
127    College of American Pathologists proficiency testing survey participants [5]. This study
128    examined the effect of HbE on HbA1c measurement across the clinically important measurement
129    range by comparing against metrologically traceable reference values determined by a chemical
130    metrology laboratory using IDMS measurements. Using this statistical approach, the effect of
131    HbE on the methods can be examined relative to the normal hemoglobin across a range of
132    concentration, which ameliorates the effects of inter-method calibrator bias.
133

134    The Cobas B 101 method showed significant positive bias across the measurement range
135    investigated in the presence of heterozygous HbE. This finding extended the observation of
136    significant positive bias in the Cobas B 101 method in a previous study that examined only a
137    single patient sample [6]. This finding is contrary to prior published manufacturer's claim, which
138    indicated no significant analytical interference by heterozygous HbE [7]. The discrepancy may
139    be explained by the use of an acceptability criteria of ±10% relative difference [7], which is
140    significantly wider than the clinical standards of ± 6% required by the laboratory profession [5].
141    Laboratory practitioners should carefully communicate the significant positive interference in the
142    Cobas B 101 method due to heterozygous HbE to the clinical user.
143

144    The significant positive bias observed in the Cobas B101 method is analytically unexpected. The
145    Cobas B 101 method is a point-of-care assay that applies the principle of turbidimetric
146    immunoinhibition. In general, immunoassays are thought to be more resilient against
147    heterozygous HbE since the amino acid substitution is far from the N-terminus of the β chain
148    where HbA1c glycation and antibody binding occur [4]. The cause of this discrepancy remains
149    unclear at present.
150

151    On the other hand, the Variant II Turbo 2.0 method showed proportional positive bias in the
152    presence of HbE. This finding is consistent with a previous report by Sthaneshwar et al. [8]. At
153    lower HbA1c concentration, the positive relative bias is large (10%) and reduces at higher
154    HbA1c concentrations. Interestingly, a previous publication reported no significant interference
155    with HbE, despite having 1 out of 11 samples exceeding the acceptability criteria of ±10%
156    relative difference in their internal evaluation [9]. The positive interference from heterozygous
157    HbE on the Variant II Turbo 2.0 method may be related to the incomplete cation-exchange

158 chromatography separation. This potentially leads to overlapping HbE and HbA peaks that are
159 sub-optimally resolved by the integration function of the algorithm.
160
161 These findings are of clinical concern for two reasons. Firstly, the acceptability criteria used by
162 regulatory body is wider compared to the clinical requirements of routine laboratories. A 10%
163 acceptability criteria implies that a relative difference of such magnitude is clinically acceptable.
164 However, a 10% relative difference in HbA1c value can significantly alter the clinical
165 interpretation of the results of individual patients. At a population level, the mean of HbA1c lies
166 close to the clinical diagnostic threshold of 5.6% for pre-diabetes [10, 2]. The significant bias
167 will lead to over-diagnosis of diabetes, and the consequent unnecessary treatment and erroneous
168 allocation of healthcare resources [10]. As such, regulatory bodies should consider aligning their
169 acceptability criteria with professional bodies to maintain the quality chain from manufacturer to
170 laboratory and clinical end-users.
171
172 Secondly, the finding of significant bias meant that individual laboratory must exercise care
173 when selecting a method. Additionally, in regions where a particular hemoglobin variant is
174 prevalent, it may be prudent for the laboratory to verify the prior data, especially when its
175 clinical requirements differ significantly from the manufacturer's acceptability criteria. However,
176 such verification exercise is often beyond the means of individual routine laboratories. This can
177 be overcome by forming a collaborative network of laboratories to jointly evaluate the methods.
178 When such exercise is performed, it is desirable to employ a reference laboratory method that is
179 not influenced by the presence of hemoglobin variant in question.
180
181 Nevertheless, access to such reference laboratory method is limited. Increased reporting of
182 hemoglobin variant interference in the literature will help laboratory practitioners make more
183 informed decisions and assist manufacturers in improving their analytical methods. It may be
184 necessary to periodically re-evaluate hemoglobin variant interference as a manufacturer may
185 reformulate their reagents or modify their analytical methods, particularly for the CE-HPLC [11].
186

## Conclusions

188
189 There is currently no consensus on how laboratory should manage hemoglobin variants that are
190 incidentally detected during HbA1c measurements [12]. Some hemoglobin variants can interfere
191 with HbA1c measurements leading to spurious results. Others may alter the lifespan of the red
192 blood cells, leading to an altered glycation rate of the hemoglobin. An example of this is
193 homozygous hemoglobin S that causes sickle cell disease. It is associated with shortened red
194 blood cell lifespan, which causes lower HbA1c values relative to the ambience glucose. As such,
195 it is advantageous to communicate the presence of hemoglobin variants to the clinicians to help
196 them optimally interpret the HbA1c values. Additionally, such information also provides an
197 opportunity for work up of significant hemoglobinopathy.

198

199 In general, it is desirable to avoid the use of methods that may be significantly interfered by the
200 hemoglobin variant that is prevalent in the population served. This is particularly true for
201 laboratory methods such as CE-HPLC, where the presence of hemoglobin variants may be
202 inferred only by careful manual reading of the chromatograms by skilled technologists. It is
203 desirable to avoid reporting an HbA1c result with known hemoglobin variant interference. When
204 detected, alternative method not affected by the hemoglobin variant should be used to report the
205 HbA1c instead. Alternate biomarker such as fructosamine may also be considered. However,
206 such workflows requires access to alternate instruments or esoteric biomarkers, which may not
207 even be readily available to most laboratories.

208

209 The use of non-separative laboratory method such as the immunoassays for HbA1c measurement
210 may mask an undetected interfering hemoglobin variant. At the same time, immunoassays are
211 also liable to interfering antibodies [13]. Both of these may lead to erroneous reporting that can
212 evade laboratory detection. The use of devices with such test principles in the point of care
213 setting is considered an increased risk as laboratory supervision may be limited. As such
214 clinicians should remain highly vigilant against clinically discordant HbA1c.

Difference in HbA1c values.

The values are derived using the regression equations between the commercial methods and the isotope dilution mass spectrometry reference method for samples with heterozygous HbE and normal haemoglobin at 6% and 9% concentrations. All HbA1c are reported in National Glycohemoglobin Standardization Program units. An a priori clinical significance was set at 6% relative difference.

| Routine laboratory Method | Manufacturer | At HbA1c = 6% measured by IDMS | | | At HbA1c = 9% measured by IDMS | | |
|---|---|---|---|---|---|---|---|
| | | Normal hemoglobin | Heterozygous HbE | % Difference | Normal hemoglobin | Heterozygous HbE | % Difference |
| Tina Quant HbA1c Gen 3.0 | Roche Diagnostics | 5.6 | 5.7 | -0.9 | 8.6 | 8.5 | 1.7 |
| Cobas B 101 | Roche Diagnostics | 6.2 | 5.8 | 6.4 | 9.2 | 8.6 | 7.4 |
| D100 | Bio-Rad Laboratories | 5.8 | 5.7 | 0.3 | 8.4 | 8.4 | 0.4 |
| Variant II Turbo HbA1c 2.0 | Bio-Rad Laboratories | 6.2 | 5.6 | 9.9 | 8.9 | 8.6 | 4.4 |
| DCA Vantage | Siemens Healthcare | 5.7 | 5.7 | 0.0 | 8.7 | 8.4 | 2.6 |
| HbA1c Advance | Beckman Coulter Inc. | 5.5 | 5.6 | -1.9 | 8.3 | 8.2 | 0.9 |

# Figure 1

Passing-Bablok regression analysis of HbA1c measurements on samples with heterozygous HbE (solid line) and normal hemoglobin (dash lines).

The dotted lines are the 95% confidence intervals of the regression. All HbA1c are reported in National Glycohemoglobin Standardization Program (%) units.
