ABSTRACT

Given a directed graph $G = (V, E)$, a feedback vertex set is a vertex subset C whose removal makes the graph G acyclic. The feedback vertex set problem is to find the subset C^* whose cardinality is the minimum. As a general model, this problem has a variety of applications. However, the problem is known to be NP-hard, and thus computationally challenging. To solve this difficult problem, this paper develops an iterated dynamic thresholding search algorithm, which features a combination of local optimization, dynamic thresholding search, and perturbation. Computational experiments on 101 benchmark graphs from various sources demonstrate the advantage of the algorithm compared with the state-of-the-art algorithms, by reporting record-breaking best solutions for 24 graphs, equally best results for 75 graphs, and worse best results for only 2 graphs. We also study how the key components of the algorithm affect its performance of the algorithm.

Keywords: Feedback vertex set; Dynamic thresholding search; Descent search; Heuristic.

INTRODUCTION

Given a directed graph $G = (V, E)$, where V denotes the set of vertices and E the set of edges, a feedback vertex set (FVS) is a vertex subset $C \subset V$ whose removal leads to an acyclic graph. The feedback vertex set problem (FVSP) aims to identify a FVS of minimum cardinality. In other words, we want to remove the fewest vertices to make the graph acyclic.

The decision version of the FVSP is one of the 21 nondeterministic polynomial-time complete (NP-complete) problems, which were first proved in the early 1970s (Cook, 1971; Karp, 1972). Its broad applications include very large scale integration circuit design (Festa et al., 1999), deadlock detection (Wang et al., 1985; Leung and Lai, 1979), program verification (Seymour, 1995), Bayesian inference (Bar-Yehuda et al., 1998), operating systems (Silberschatz et al., 2006) and complex network systems (Liu et al., 2011). A typical application of the FVSP is to control the state of a complex network system, making the system to change from any given state to an expected state by controlling a minimal subset of vertices from the outside. For instance, Mochizuki et al. (2013), Fiedler et al. (2013) and Zhao et al. (2020) investigated FVS-based control mechanisms. This FVS approach proves to be suitable when only the network formation is known, while the functional form of the governing dynamic equations are ambiguous (Zhao et al., 2020). Studies also showed that this approach needs to remove fewer vertices than other structure-based methods in many cases (e.g., (Zañudo et al., 2017)).

Figure 1(a) shows a directed graph G with 5 vertices $\{a, b, c, d, e\}$. Figure 1(b) displays an arbitrary FVS $\{a, b, d\}$ with a cardinality of 3, while Figure 1(c) presents an optimal FVS $\{b, c\}$ with a minimum cardinality of 2.

Some approximation algorithms were proposed for the FVSP to provide solutions of provable quality. Erdős and Pósa (1962) presented an algorithm with an approximation ratio of $2 \log n$ ($n = |V|$). Later,

Figure 1. Random FVS and optimal FVS (the vertices of FVS are in orange and the other vertices are in blue). (a) A given graph G ; (b) A random FVS $\{a, b, d\}$; (c) An optimal FVS $\{b, c\}$.

Monien and Schulz (1981) improved the approximation ratio to $\sqrt{\log n}$. Even et al. (1998) realized an approximation factor of $O(\log \tau \log \log \tau)$ on directed graphs, where τ is the size of a minimum FVS for the input graph. Other polynomial time approximation algorithms for the FVSP in tournament graphs include those presented by Cai et al. (2001), Mnich et al. (2015) and Lokshantov et al. (2021).

From the perspective of solution methods for the FVSP applied to the ISCAS89 benchmark instances (up to 1728 vertices), several exact algorithms combined with graph reduction have been proposed. Specifically, Levy and Low (1988) presented an exact reduction based on the graph structure and proved its equivalence to the original graph. Based on the exact reduction of Levy and Low (1988), Orenstein et al. (1995) proposed graph partitioning methods with new reduction operations, which achieved optimal results on all the ISCAS89 benchmark instances within 2 CPU hours on a Sun-4 station. Lin and Jou (1999) investigated the branch-and-bound algorithm that considers the exact reduction of Orenstein et al. (1995), which could find the optimal results for the ISCAS89 benchmarks in less than 3 seconds on a SUN-UltraII workstation. There are many vertices whose in-degrees or out-degrees are 0 or 1 in the ISCAS89 benchmark instances. The average reduction ratio (the sum of the deleted vertices/the sum of vertices of a given graph) of these reduction approaches is 72.48%, implying that these benchmark instances are easy for modern FVSP algorithms. Hence, we report in this work computational results not only on these ISCAS89 instances, but also on more challenging benchmark instances. Some theoretical exact algorithms were reported without experimental validation. For example, Razgon presented a backtrack algorithm that solved the FVSP in time $O(1.8899^n)$ (Razgon, 2006) and a branch-and-prune algorithm requiring $O(1.9977^n)$ time (Razgon, 2007). Fomin et al. (2006) developed a branching algorithm with a time complexity of $O(1.7548^n)$. Some exact algorithms were also proposed specifically for tournament graphs (Moon, 1971; Gaspers and Mnich, 2013; Fomin et al., 2019).

Parameterized algorithm is another popular approach to solve the FVSP. Chen et al. (2008) solved the FVSP in time $O(4^k k! nm)$, where m is the number of edges of the graph, and k is the largest number of selected vertices. Lokshantov et al. (2018) proposed an algorithm whose running time is $O(4^k k! k^5 (n + m))$. Bonamy et al. (2018) proved that the running time could be reduced to $2^{O(k)} n^{O(1)}$ for planar directed graphs.

Considering the high difficulty of the FVSP, exponential time exact algorithms can only be applied to specific graphs (such as the ISCAS89 benchmark instances). Therefore, heuristic algorithms are usually adopted to obtain sub-optimal solutions within a reasonable time frame to tackle more general and complicated graphs. Pardalos et al. (1998) introduced the first heuristic algorithm for the FVSP, based on the greedy randomized adaptive search procedure (GRASP) approach. Galinier et al. (2013) presented a simulated annealing (SA) that applies the INSERT operation and a fast neighborhood evaluation technique. Besides, they combined their SA algorithm with an exact reduction technique (Red+SA). They performed extensive experiments on 40 random instances (1000 runs for SA and 30 runs for Red+SA) and showed that both SA and Red+SA fully dominate the GRASP algorithm. Zhou (2016) constructed a spin glass model and implemented a belief propagation-guided decimation (BPD) algorithm, which initially declares all vertices as active and repeats the fixing-and-updating procedure until all vertices are turned into inactive. The BPD algorithm obtained the same best known results as SA on the set of instances in Galinier et al. (2013). Tang et al. (2017) put forward a variant of SA by introducing a non-uniform neighborhood sampling strategy (SA-FVSP-NNS). However, experiments proved that SA in Galinier et al. (2013) dominates the SA-FVSP-NNS for 30 runs with 39 better results and 1 equal result. In summary, according to the literature (Galinier et al., 2013; Zhou, 2016; Tang et al., 2017), among all existing practical algorithms for the FVSP, the Red+SA, SA (Galinier et al., 2013) and BPD (Zhou, 2016) algorithms are the top algorithms for the problem. Thus, we use them as our main reference approaches

for this study. Finally, Qin and Zhou (Qin and Zhou, 2014) presented the simulated annealing local search algorithm (SALS), which is an adaptation of the SA algorithm of Galinier et al. (2013) to the undirected FVS problem and showed its effectiveness on large random undirected graphs. We adopt SALS as an additional reference method for our study on undirected graphs.

The above literature review demonstrates that progresses were continually realized since the introduction of the FVSP. However, few effective heuristic algorithms exist, able to solve the problem in a satisfactory manner. This work partially fills the gap by presenting an iterated dynamic thresholding search (IDTS) algorithm for the FVSP. The algorithm includes three exact reduction rules to simplify the graph, a greedy initialization to generate initial acyclic subgraphs, a dynamic thresholding local search to reduce the size of the acyclic subgraph, and a learning-based perturbation to reconsider the vertices that would have been wrongly regarded as feedback vertices.

Experiments are performed on 101 benchmark instances from various sources to assess the IDTS algorithm. For the 70 instances with unknown optima, IDTS is able to improve 24 best-known solutions and attain the best-known results for 44 other instances. Only for 2 instances, IDTS reports a worse result. Moreover, IDTS easily attains the known optimal results for all 31 ISCAS89 benchmark instances.

The remainder of this paper is arranged as follows. Section 1 introduces useful basic notations and fitness function of the FVSP. Section 2 is a preliminary presentation. Section 3 explains the components of the IDTS algorithm. Section 4 evaluates the algorithm with computational results. Section 5 studies critical components of the proposed algorithm, and Section 6 provides conclusions.

1 BASIC NOTATIONS AND FITNESS FUNCTION

This section introduces relevant basic definitions, solution representation and fitness function, which are necessary for presenting the proposed algorithm.

1.1 Basic definitions

Given a directed graph $G = (V, E)$, basic definitions that are useful for describing the proposed IDTS algorithm are presented as below.

Definition 1: a *critical vertex* of G is a vertex that belongs to a FVS. We use C to denote the set of critical vertices that have been detected. C is a FVS only when all vertices of the FVS are detected.

Definition 2: an *uncritical vertex* is a vertex that does not belong to a FVS. We use U to denote the set of uncritical vertices, and $V = C \cup U, C \cap U = \emptyset$.

Definition 3: a *redundant vertex* refers to a vertex that is recognized as critical or uncritical according to the exact rules proposed by Levy and Low (1988). We use V_r to denote the set of redundant vertices that have been detected, C_r to denote the set of critical vertices of V_r , U_r to denote the set of uncritical vertices of V_r , and $V_r = C_r \cup U_r, C_r \cap U_r = \emptyset$.

Definition 4: V_0 refers to the set of residual vertices after applying the removal exact algorithm proposed by Levy and Low (1988). C_0 denotes the set of feedback vertices of V_0 (that is, all vertices of a FVS are detected and belong to C_0), U_0 denotes the set of non-feedback vertices of V_0 , and $V_0 = C_0 \cup U_0, C_0 \cap U_0 = \emptyset$. Levy and Low (1988) proved that the FVS of the reduced graph plus the FVS removed in the reduction process composes the FVS of the original graph. Let C_r be the set of vertices removed in the reduction process, and C_0^* be the minimum FVS of the reduced graph $G = (V_0, E_0)$, where $E_0 = V_0 \times V_0 \cap E$. Then, $C_r \cap C_0^* = \emptyset$ and $C_0^* \cup C_r$ is a minimum FVS of the given graph $G = (V, E)$. In this case, only the feedback vertices of the reduced graph need to be found out.

In summary, the vertex set V of G consists of 2 disjoint sets $\{V_0, V_r\}$ or 4 disjoint sets $\{C_0, U_0, C_r, U_r\}$.

Definition 5: a *directed acyclic graph* (DAG) (Bangjensen and Gutin, 2008) is a directed graph with no directed cycles.

Vertices in each DAG are in a topological ordering where the starting point of every directed edge is ahead of its terminal point (Galinier et al., 2013). For a vertex set $U \subset V$, we notice that the induced subgraph $G_U = (U, E_U)$, $E_U = U \times U \cap E$ is acyclic if and only if $V \setminus U$ is a FVS. Hence, the objective of the FVSP is to find the set U that has the maximum cardinality to make $G_U = (U, E_U)$ acyclic.

Figure 2 presents an example illustrating these basic definitions. For the given graph $G = (V, E)$, let $\{a, b, d, h\}$ be the current FVS. The set of critical vertices C is the current FVS $\{a, b, d, h\}$, and the set of remaining vertices is the set of uncritical vertices U , i.e., $\{c, e, f, g, i, j\}$. According to the rules in subsection 3.2, h can be recognized as a critical vertex ($C_r = \{h\}$, purple vertex) and f, g, i, j as uncritical vertices ($U_r = \{f, g, i, j\}$, dark blue vertices). Thus the set of redundant vertices V_r is $\{f, g, h, i, j\}$, and

the set of residual vertices V_0 is $\{a, b, c, d, e\}$. V_0 can be divided into $C_0 = \{a, b, d\}$ (orange vertices) and $U_0 = \{c, e\}$ (blue vertices). Clearly, the graph induced by the vertices in $U = \{c, e, f, g, i, j\}$ is a DAG without directed cycles.

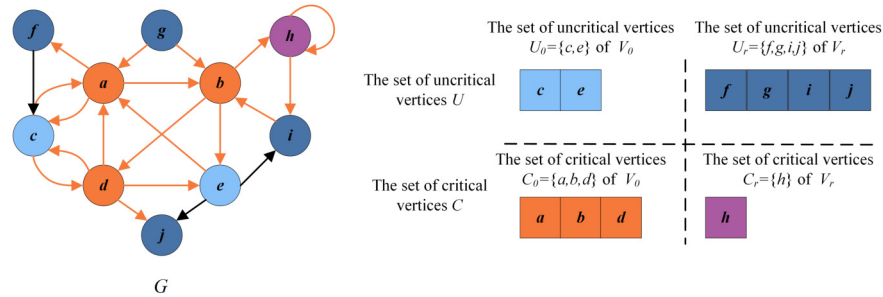

Figure 2. An example for illustrating basic definitions.

1.2 Solution representation and fitness function

The solution representation and fitness function of the FVSP are given as follows.

Solution representation: the constraint of the FVSP is that there is no cycle in U_0 after removing the set of redundant vertices $C_r \cup U_r$ and the set of critical vertices C_0 . To quickly assess the number of cycles in U_0 after each neighborhood operation, the number of conflicts (see Section 2) is taken as the number of cycles (Galinier et al., 2013). Let π be an assignment of the vertices of U_0 to the positions $\{1, 2, \dots, |U_0|\}$, and thus the permutation π denotes the candidate solution (Galinier et al., 2013).

Fitness function: To evaluate the quality of the FVS C , the evaluation or fitness function counts the number of vertices in C . Recall that U_r is the set of uncritical vertices of the redundant vertices and π is the corresponding permutation solution of C . The fitness function f_0 (to be minimized) is given by

$$\text{Minimum } f_0(\pi) = |V| - |U_r| - |\pi| \quad (1)$$

Thus, the minimization of the function f_0 is equal to the maximization of the fitness function f , which is expressed as:

$$\text{Maximize } f(\pi) = |\pi| \quad (2)$$

2 PRELIMINARIES

In this section, we introduce two properties of FVS: number of conflicts and INSERT operator position.

Number of conflicts: u and v are a pair of conflicting vertices if v is ahead of u in permutation π and there is a directed edge from u to v . The number of conflicting vertex pairs of the permutation π is the number of conflicts. Let $\text{edge}(u, v) = 1$ if there is a directed edge from u to v . Otherwise, $\text{edge}(u, v) = 0$. We use $c(u, v)$, where $u, v \in \pi, u \neq v, \text{edge}(u, v) = 1$, to indicate whether u and v form a conflicting vertex pair as follows

$$c(u, v) = \begin{cases} 1, & \pi_v < \pi_u \\ 0, & \pi_v > \pi_u \end{cases} \quad (3)$$

where π_v represents the position chosen for vertex v in permutation π . Then, the number of conflicts $g(\pi)$ is given by

$$g(\pi) = \sum_{u, v \in \pi} c(u, v) \quad (4)$$

Thus, for a conflict-free solution π , $g(\pi) = 0$ holds. The time complexity to compute $g(\pi)$ is $O(d_{max})$, where d_{max} denotes the largest degree of a vertex in the graph. Clearly, the number of conflicts is more than the actual number of cycles for the same solution.

Figure 3 displays two cases between the number of conflicts and the number of cycles. The left part of Figure 3(a) indicates the current remaining vertex set U_0 of the given G , and the right part is its corresponding permutation $\pi = \{a, b, d\}$. In this permutation, no directed edge from b to a (d to b or to a) exists. Thus, there is no conflicting pair, meaning the number of cycles is 0. Figure 3(b) shows a situation where the number of conflicts is more than the number of cycles. Vertex b is behind vertex d in the solution permutation $\pi = \{d, a, b\}$ on the right side, and there is a directed edge from b to d . Accordingly, vertex b and vertex d are conflicting, and the number of conflicts is 1, which exceeds the number of cycles (0).

Figure 3. An example of conflicts in a solution. (a) The number of conflicts is equal to the number of cycles; (b) The number of conflicts exceeds the number of cycles.

INSERT operator position: The INSERT operator inserts a vertex v from the uncritical vertex set to two possible positions in π (Galinier et al., 2013); one is closely behind its numbered in-coming neighbors (named $i_-(v)$), and the other is just ahead its numbered out-going neighbors (named $i_+(v)$). The number of conflicting pairs after the insertion operation at the above two positions is calculated respectively, and the position with less conflicting pairs is selected.

We use $\langle v, i_-(v), i_+(v) \rangle$ to represent such a move, and $\pi \oplus \langle v, i_-(v), i_+(v) \rangle$ to stand for the neighboring solution generated by applying the INSERT move to π . Moreover, $g(\pi \oplus \langle v, i_-(v), i_+(v) \rangle)$ refers to the number of conflicts after inserting the vertex $v \in C_0$. $N_I(\pi)$ contains the vertices that satisfy the condition $g(\pi \oplus \langle v, i_-(v), i_+(v) \rangle) = 0$. That is, the vertex v to be inserted has to be a vertex that will not cause any conflict after being inserted into π . $N_I(\pi)$ can be expressed as

$$N_I(\pi) = \{v : g(\pi \oplus \langle v, i_-(v), i_+(v) \rangle) = 0, v \in C_0\} \quad (5)$$

3 ITERATED DYNAMIC THRESHOLDING ALGORITHM FOR THE FVSP

3.1 Basic steps

This section introduces the iterated dynamic thresholding algorithm for solving the FVSP, which is composed of five main procedures as shown in Algorithm 1.

Reduction procedure: IDTS adopts a set of conventional reduction rules (Levy and Low, 1988) to simplify the given graph G . Firstly, a set of redundant vertices V_r (made up of the set of critical vertices C_r and the set of uncritical vertices U_r) is confirmed according to those rules. Then, the redundant vertices and related edges (whose starting or ending vertex is a redundant vertex) are deleted, reducing the input graph $G = (V, E)$ to the reduced graph $G = (V_0, E_0)$ (see Section 3.2).

Initialization procedure: this procedure greedily chooses a vertex (Cai et al., 2006) such that its insertion to π does not increase the number of cycles. This process continues until no such vertex can be inserted (see Section 3.3).

Local search procedure: this procedure consists of two complementary search stages: a dynamic thresholding search stage (diversification) to extend the search to unexplored regions, and a descent search stage (intensification) to find new local optimal solutions with improved quality. These two stages alternate until the best-found solution cannot be further improved for ω continuous local search rounds (see Section 3.4).

Perturbation procedure: When the search is considered as trapped in a deep local optimum, the perturbation procedure is initiated to move some specifically identified vertices between U_0 and C_0 to relieve the search from the trap. The solution perturbed is then adopted to start the next round of the local search procedure (see Section 3.5).

Algorithm 1: IDTS algorithm for the FVSP

Input: A directed graph $G = (V, E)$, cutoff time, and search depth ω
Output: The smallest FVS of size $|C^*|$

```

1  $\pi \leftarrow \emptyset, \pi^* \leftarrow \emptyset, |C^*| \leftarrow |V|$ 
2  $(G, C_r, U_r) \leftarrow \text{Reduction\_phase}(G)$  /*Section 3.2*/
3  $\pi \leftarrow \text{Greedy\_Initialization}(G)$  /*Section 3.3*/
4  $\pi^* \leftarrow \pi$ 
5 while The cutoff time is not reached do
6    $\pi \leftarrow \text{Local\_search}(G, \pi, \pi^*, \omega)$  /*Section 3.4*/
7    $\pi \leftarrow \text{Perturbation}(\pi)$  /*Section 3.5*/
8   if  $f(\pi) > f(\pi^*)$  then
9      $\pi^* = \pi$ 
10  end
11 end
12  $C^* \leftarrow \text{Recovery\_phase}(G, C_r, U_r, \pi^*)$  /*Section 3.6*/
13 return  $|C^*|$ 
```

Recovery procedure: If the best solution ever found cannot be improved after γ continuous local search rounds and the perturbation phase, the search then terminates and the recovery procedure starts. The best solution (minimum feedback vertex set) found in the search procedure is recorded as C_0^* and returned as the input of the recovery procedure. The current reduced graph $G = (V_0, E_0)$ is recovered to the original graph $G = (V, E)$, and the FVS C_0^* for $G = (V_0, E_0)$ is correspondingly projected back to $C_0^* \cup C_r$ for $G = (V, E)$ (see Section 3.6).

3.2 Reduction procedure

The graph reduction procedure follows three rules when traversing all vertices in a given graph $G = (V, E)$ and processes those that satisfy any rule proposed by Levy and Low (1988). The three reduction rules are as follows.

Rule 1: If the in-degree (out-degree) of a vertex v is 0, that is, v is an uncritical vertex, then v and all its edges can be deleted without missing any optimal feedback vertex of G . Such vertices are added into the redundant uncritical set U_r ($U_r = U_r \cup \{v\}$). For example, as shown in Figure 4(b), the edges of the vertex g whose in-degree is 0, and those of the vertex j whose out-degree is 0 can be deleted.

Rule 2: If the in-degree (out-degree) of a vertex v is 1, and there is no self-loop, then vertex v can be merged with the unique precursor (successor) vertex without missing any optimal feedback vertex of G . The merging process is that all edges connected to the vertex v are linked to the unique precursor (successor) vertex of v . Such vertices are added into the redundant uncritical set U_r ($U_r = U_r \cup \{v\}$). Figure 4(c) displays that the vertex f with an in-degree of 1 can be merged with the precursor vertex a , and the vertex i with an out-degree of 1 can be merged with the successor vertex b .

Rule 3: If a self-loop exists for a vertex v , then v and all its edges can be deleted and recovered as a part of the feedback vertex set without losing any optimal feedback vertex of G . Such vertices are added into the redundant uncritical set C_r ($C_r = C_r \cup \{v\}$). As shown in Figure 4(d), the self-loop vertex h and its connected edges can be deleted.

After deleting the sets U_r and C_r , the remaining vertex set $V_0 = V \setminus (U_r \cup C_r)$, and the reduced subgraph $G = (V_0, E_0)$, ($E_0 = (V_0 \times V_0 \cap E)$). After obtaining reduced G , the greedy initialization is used to generate an initial solution for it.

3.3 Greedy initialization

Given the reduced subgraph $G = (V_0, E_0)$, its critical vertex set is defined as C_0 , and the uncritical vertex set as U_0 . Recall that π is an assignment of the vertices of U_0 to the positions $\{1, 2, \dots, |U_0|\}$. We initialize $C_0 = V_0$, $\pi = \emptyset$. Then, π is iteratively extended in the greedy procedure by inserting a minimum-score vertex v of C_0 until no vertex can be inserted.

1) Calculate $N_I(\pi)$: recall that $N_I(\pi)$ contains the vertices that satisfy $g(\pi \oplus < v, i_-(v), i_+(v) >) = 0$. Thus, we only has to traverse all vertices and add the vertex whose $g(\pi \oplus < v, i_-(v), i_+(v) >) = 0$ into $N_I(\pi)$.

Figure 4. An example of reduction operation for the given graph G . (a) The given graph G ; (b) Applying Rule 1 to delete g (in-degree=0) and j (out-degree=0); (c) Applying Rule 2 to delete f (in-degree=1) and i (out-degree=1); (d) Applying Rule 3 to delete h (self-loop).

246 2) Select one vertex: choose a vertex v with the minimum score (Equation 6, (Cai et al., 2006)) in
247 $N_I(\pi)$ and insert it into the current permutation $\pi \leftarrow \pi \oplus \langle v, i_-(v), i_+(v) \rangle$.

$$score(v) = |deg^-(v) + deg^+(v)| - \lambda \times |deg^-(v) - deg^+(v)| \quad (6)$$

248 where $deg^-(v)$ and $deg^+(v)$ are the in-degree and the out-degree of v respectively, and λ is a parameter
249 ($\lambda = 0.3$ according to Cai et al. (2006)).

250 3) Update $N_I(\pi)$: after inserting the vertex v into π , we only have to recalculate the number of conflicts
251 $g(\pi \oplus \langle u, i_-(u), i_+(u) \rangle)$ of its neighbors $u \in N_I(\pi)$ according to Equation 4. Any vertex satisfying
252 $g(\pi \oplus \langle u, i_-(u), i_+(u) \rangle) \neq 0$ will be eliminated from $N_I(\pi)$. Thus, the complexity of this updating step
253 is $O(d_{max}^2)$, where d_{max} is the largest degree of a vertex in the graph. This process continues until no
254 vertex can be inserted into π , i.e., $N_I(\pi) = \emptyset$.

255 In this initialization, a legal conflict-free π with a certain quality can be obtained, and further improved
256 in the dynamic thresholding search stage of the algorithm.

Algorithm 2: Greedy initialization for FVSP

Input: A reduced graph $G = (V_0, E_0)$

Output: A solution permutation π

```

1  $\pi \leftarrow \emptyset$ 
2  $N_I(\pi) \leftarrow \emptyset$ 
3 for each  $v \in V_0$  do
4   Calculate  $N_I(\pi)$  according to Eq. (5)                                /*Step 1*/
5 end
6 while  $N_I(\pi) \neq \emptyset$  do
7   Choose a vertex  $v \in N_I(\pi)$  with the minimum score according to Eq. 6 and insert it into  $\pi$  /*Step 2*/
8   Update  $N_I(\pi)$                                                          /*Step 3*/
9 end
10 return  $\pi$ 

```

257 To explain this process, we consider the reduced graph $G = (V_0, E_0)$ in Figure 4(d) (with vertices
258 $\{a, b, c, d, e\}$). For Figure 4(d), $C_0 = \{a, b, c, d, e\}$, $U_0 = \pi = \emptyset$ and $g(\pi \oplus \langle v, i_-(v), i_+(v) \rangle) = 0, \forall v \in C_0$.
259 Figure 5 shows how the greedy procedure works. Firstly we calculate $N_I(\pi) = \{a, b, c, d, e\}$. Then, it

is detected that $score(a) = 4.7, score(b) = 4, score(c) = 4, score(d) = 4.7, score(e) = 4$ according to Eq. (6). Finally, we select a vertex from $N_I(\pi)$ with the minimum score and insert it into π . Suppose we select vertex e for insertion. $N_I(\pi)$ is updated to $\{a, c, d\}$. As shown in Figure 5(a), the solution after the first greedy insertion is the permutation $\pi = \{e\}$. By repeating the above steps until $N_I(\pi) = \emptyset$, we obtain the local optimal permutation $\pi = \{e, c\}$ (Figure 5(b)). Meanwhile, this process may unfortunately misclassify critical vertices in permutation π . For example, the optimal permutation of Figure 4(d) is $\{d, e, a\}$ with the set of critical vertices $\{b, c\}$, while the local optimal permutation of Figure 5(b) is $\{e, c\}$ with the set of critical vertices $\{a, b, d\}$.

Figure 5. An example of greedy initialization. (a) The solution $\pi = \{e\}$ and the set of critical vertices $C_0 = \{a, b, c, d\}$ after the first greedy insertion; (b) Local optimal solution $\pi = \{e, c\}$ and the set of critical vertices $C_0 = \{a, b, d\}$.

3.4 Local search

The local optimization aims to improve the initial permutation provided by the greedy initialization, and it consists of two stages. The first stage (dynamic thresholding search) brings diversity as it accepts equivalent or worse solutions (line 4 of Algorithm 3), and the second stage applies a descent search that accepts only better solutions (line 5 of Algorithm 3) to guarantee a concentrated and directed search. These two stages alternate until the best found solution cannot be further improved for ω local search rounds.

Algorithm 3: Local Search

Input: Reduced graph $G = (V_0, E_0)$, solution π , best solution π^* , search depth ω
Output: Improved solution π

```

1  $NoImprove \leftarrow 0$                                      /*Indicate the times of  $\pi^*$  being improved*/
2 while  $NoImprove < \omega$  do
3    $NoImprove \leftarrow NoImprove + 1$ 
4    $(\pi, \pi^*, NoImprove) \leftarrow Dynamic\_thresholding\_search(\pi, \pi^*, NoImprove)$    /*Section 3.4.1*/
5    $(\pi, \pi^*, NoImprove) \leftarrow Descent\_search(\pi, \pi^*, NoImprove)$              /*Section 3.4.2*/
6 end
7 return  $\pi$ 

```

3.4.1 The dynamic thresholding search stage

There are many successful applications of dynamic thresholding search (Dueck and Scheuer, 1990; Moscato and Fontanari, 1990) (e.g. the frequency assignment (Diane and Nelson, 1996), quadratic multiple knapsack problem (Chen and Hao, 2015), heterogeneous fixed fleet vehicle routing problem (Tarantilis et al., 2004), and others (Chen and Hao, 2019; Zhou et al., 2021; Lai et al., 2022)).

In this work, three basic move operators (DROP, INSERT and SWAP) are adopted in the thresholding search stage that accepts both equivalent and better solutions. DROP deletes a vertex from the current permutation π and move it to C_0 ; INSERT extends the current permutation π by introducing a new vertex; SWAP deletes a vertex v from the current permutation π and inserts a vertex u into π .

Based on these three move operators, dynamic thresholding search (DTS) adopts both the vertex-based strategy and the prohibition mechanism to balance the exploration and exploitation of the search space. In each search round at this stage, the algorithm first randomly visits all vertices in V_0 one by one. For each vertex v considered, the set of candidate move operators is executed depending on whether the vertex is in or out of the permutation π . If the objective value of the obtained solution is not worse than the best solution found ever to a certain threshold, the move operation on the vertex is executed. Otherwise, the

Algorithm 4: The dynamic thresholding search

Output: Solution π , best solution π^* , the iterations without improvement $NoImprove$

```

1 Randomly shuffle all vertices in  $V_0$ 
2 for each  $v \in V_0$  do
3   if  $v \notin \pi$  then
4     if the number of conflicts after inserting  $v$  into  $\pi$  is 0 then
5       Insert  $v$  into  $\pi$                                      /* INSERT operator */
6       if  $f(\pi) > f(\pi^*)$  then
7          $\pi^* \leftarrow \pi, NoImprove \leftarrow 0$ 
8       end
9     else if  $v$  only conflicts with  $u \in \pi$  and has not been involved in any SWAP operation then
10      Remove  $u$  from  $\pi$  and insert  $v$  into  $\pi$                  /* SWAP operator */
11   else
12     Calculate  $NM(v)$  according to Eq. (7)
13     if  $NM(v) \neq \emptyset$  and  $v$  has not been involved in any SWAP operation then
14       Randomly select a vertex  $u$  from  $NM(v)$ 
15       Remove  $v$  from  $\pi$  and insert  $u$  into  $\pi$              /* SWAP operator */
16     else if  $f(\pi) - 1 > f(\pi^*) - \delta$  then
17       Remove  $v$  from  $\pi$                                    /* DROP operation */
18   end
19 end
20 return  $\pi, \pi^*, NoImprove$ 

```

operation is rejected. Each time a move is taken, the concerned vertex is marked as tabu and forbidden to be moved again during the next tt iterations (tt is the tabu tenure). This process continues until all vertices of V_0 are traversed.

1) If v is outside π (i.e., $v \in C_0$), the candidate move operator set consists of INSERT and SWAP. INSERT is applied first as it improves the solution quality. Then SWAP is applied, which keeps the solution quality unchanged. If neither operator can be applied, DTS just skips v . INSERT can be applied if the number of conflicts of v in π is 0 (i.e., $g(\pi \oplus < v, i_-(v), i_+(v) >) = 0$). SWAP is applied if v meets two conditions simultaneously: 1) v is not involved in any SWAP operation already taken at the current round; 2) v conflicts with just one vertex u in π (i.e., $g(\pi \oplus < v, i_-(v), i_+(v) >) = 1$, and can only be swapped with u).

Similar to the INSERT operation in the greedy initialization, we adopt $g(\pi \oplus < v, i_-(v), i_+(v) >)$ for quick computation during the DTS stage. That is, we only have to update the number of conflicts of the operated vertex v and its neighbor vertices after each move operation, i.e., the updated vertex set is $\{v\} \cup \{u : (u, v) \in E \text{ and } u \in C_0\}$. For the INSERT operation, we update the number of conflicts of the vertices neighboring to v and not in π ; for the SWAP operation, we update the number of conflicts of v , u , and all vertices neighboring to u and v not in π . Thus, the time complexity of INSERT and SWAP is $O(d_{max}^2)$, where d_{max} denotes the largest degree of a vertex in the graph.

2) If v belongs to π , DROP and SWAP are the two candidate operators. SWAP is applied before DROP as SWAP does not degrade the solution quality while DROP does. If neither operation can be applied, the algorithm just skips v . SWAP can be applied only if v satisfies two conditions simultaneously: 1) v was not involved in any SWAP operation already taken at the current round; 2) the set $NM(v) \subset C_0$ of v is non-empty, which is defined as

$$NM(v) = \{u : g(\pi \setminus \{v\} \oplus < u, i_-(u), i_+(u) >) = 0, c(u, v) = 1\}. \quad (7)$$

The vertex u that is to be swapped with v is a random vertex in $NM(v)$.

DROP can be applied if it makes the number of the vertices in π still above the threshold determined by $f(\pi^*) - \delta$ after the DROP operation, where π^* is the best recorded solution and δ (a small positive integer) is a parameter. For the DROP operation, we need to update the number of conflicts of v and all vertices neighboring to v and not in the solution π . The time complexity of DROP is $O(d_{max}^2)$.

Figure 6 shows an example of the dynamic thresholding search stage. To explain this stage, we

consider the solution in Figure 5(b) as the input solution. For Figure 5(b), $C_0 = \{a, b, d\}$, $U_0 = \pi = \{e, c\}$ and $V_0 = \{a, b, c, d, e\}$. Suppose that the vertices in V_0 are randomly shuffled into $\{a, e, d, b, c\}$. As shown in Figure 6(a), since the first vertex a is outside π , INSERT and SWAP are the two candidate operators. INSERT is chosen to be applied before SWAP. The INSERT operator cannot be used since the number of conflicts of v is not 0. However SWAP can be applied since c only conflicts with a and a is not in the tabu list. As shown in Figure 6(b), for the second vertex $e \in \pi$, SWAP and DROP are the two candidate operators to be considered. SWAP is applied before DROP. SWAP can be applied since in this case $NM(e) = \{b, d\}$ and v is not forbidden by the tabu list. Thus the second vertex e is swapped with a random vertex in $NM(e)$, such as d . After that, the remaining vertices in V_0 are evaluated in the same way, while no operators can be applied to them. As a result, the improved solution is $\pi = \{d, a\}$.

Figure 6. An example of the dynamic thresholding search. (a) The solution $\pi = \{e, a\}$ and the set of critical vertices $C_0 = \{c, b, d\}$ after swapping c with a ; (b) The solution $\pi = \{d, a\}$ and the set of critical vertices $C_0 = \{c, b, e\}$ after swapping e with d .

3.4.2 The descent search stage

To complement the DTS stage where both equivalent and worse solutions are accepted, the descent search stage is subsequently applied to perform a more intensified examination of candidate solutions. Basically, this stage iteratively selects a conflict-free vertex and inserts it into the solution until such a vertex does not exist anymore.

Algorithm 5: The descent search

Input: Reduced graph $G = (V_0, E_0)$, solution π , best solution π^* , the iterations without improvement $NoImprove$

Output: Solution π , best solution π^* , the iterations without improvement $NoImprove$

```

1 while  $N_I(\pi) \neq \emptyset$  do
2   Randomly select a vertex  $u$  from  $N_I(\pi)$  and insert it into  $\pi$ 
3   if  $f(\pi) > f(\pi^*)$  then
4      $\pi^* \leftarrow \pi$ ,  $NoImprove \leftarrow 0$ 
5   end
6 end
7 return  $\pi, \pi^*, NoImprove$ 

```

Figure 7 shows an example of the descent search stage. To explain this stage, we consider the solution in Figure 6(b) as the input solution, where $C_0 = \{c, b, e\}$, $U_0 = \pi = \{d, a\}$ and $V_0 = \{a, b, c, d, e\}$. Through computation, $N_I(\pi) = \{e\}$. As shown in Figure 7, the vertex e from $N_I(\pi)$ is directly inserted into π and the best solution π^* is updated to $\{d, e, a\}$.

Figure 7. The local optimal solution $\pi = \{d, e, a\}$ and the set of critical vertices $C_0 = \{c, b\}$ of the descent search.

3.5 Perturbation procedure

As described in Section 3.4.1, the threshold search accepts worse solutions that are within a certain quality threshold from the current solution, which relieves the search from the local optimum trap. However, there is a possibility that this strategy may fail. Therefore, we introduce a perturbation strategy that comes into effect when the search falls into a deep stagnation (i.e., the best solution does not change after ω consecutive local search runs). The perturbation strategy incorporates a learning mechanism that gathers move frequencies information from the local search, which is then advantageously used to guide the perturbation.

Algorithm 6: Learning-based perturbation

Input: Solution π , the first and the second perturbation strength coefficients β_1 and β_2

Output: Perturbed solution π

// Step 1

1 $L \leftarrow \lceil (\beta_1 + \beta_2) \times |\pi| \rceil$

2 $A \leftarrow L$ vertices in π with the highest move frequencies

3 $A \leftarrow \text{sort } A$ in non-increasing order of move frequencies

4 $N_I(\pi) \leftarrow \emptyset$

// Step 2

5 **for each** $v \in A$ **do**

6 Drop the vertex v from π and record its order j in A

7 Calculate $N_I(\pi)$ according to Eq. 5

8 **if** $j > \lceil \beta_1 \times (|\pi| + 1) \rceil$ **and** $N_I(\pi) \neq \emptyset$ **then**

9 Randomly select a vertex u from $N_I(\pi)$ and insert it into π

10 **end**

11 **end**

12 **return** π

Algorithm 6 displays the perturbation procedure, which is decomposed into two steps:

Step 1: Choose and sort L vertices in π . Choose L vertices in π with the highest move frequencies and sort them in a non-increasing order of the frequencies (lines 1-3, Algorithm 6). The move frequency of each vertex v is the number of times that v has been moved during the local search, which is initially set to 0, and increases by 1 each time v is moved from one set to another.

Step 2: Drop and insert the to-be-perturbed vertices. Each vertex v ($v \in A$) is dropped, whose order j in A is recorded (line 6, Algorithm 6). If $j > \lceil \beta_1 \times (|\pi| + 1) \rceil$ and $N_I(\pi) \neq \emptyset$, randomly select a vertex u from $N_I(\pi)$ and insert it into π (lines 8-9, Algorithm 6). Recall that $N_I(\pi)$ represents the set of vertices in C_0 satisfying the condition $g(\pi \oplus \langle v, i_-(v) \rangle, i_+(v) \rangle) = 0$.

Figure 8 shows an example of the learning-based perturbation applied to a local optimal solution as shown in Figure 7, where $C_0 = \{c, b\}$ and $U_0 = \pi = \{d, e, a\}$. Suppose $L = 2$ and the chosen vertices is sorted as $A = \{e, a\}$ according to the move frequencies. The first vertex e is dropped, which leads to an intermediate perturbed solution $\pi = \{d, a\}$. Then, the second vertex a is also dropped. Since the order of a is 2, which is more than $\lceil \beta_1 \times (|\pi| + 1) \rceil = 1$ vertex, and $N_I(\pi) \neq \emptyset$, the vertex b is selected randomly from $N_I(\pi)$ and inserted into π , giving the perturbed solution $\pi = \{b, d\}$.

Figure 8. An example of the learning-based perturbation. (a) An intermediate perturbed solution $\pi = \{d, a\}$ and the set of critical vertices $C_0 = \{b, c, e\}$; (b) A perturbed solution $\pi = \{b, d\}$ and the set of critical vertices $C_0 = \{a, c, e\}$.

3.6 Recovery procedure

This is a reversed procedure of the reduction procedure. It restores the original graph $G = (V, E)$ from the reduced graph $G = (V_0, E_0)$ by adding back the removed vertices U_r and the critical vertices C_r . Levy and Low (1988) indicates that the FVS of the original G is $C = C_0 \cup C_r$. Figure 9 depicts an example that shows how the minimum FVS is determined. In the reduction procedure, $C_r = \{h\}$, $U_r = \{f, g, i, j\}$. After the search stage, $V_0 = \{a, b, c, d, e\}$ where $C_0 = \{b, c\}$, $U_0 = \{a, d, e\}$. After the recovery procedure, the FVS of the original G is $C = C_0 \cup C_r = \{b, c, h\}$.

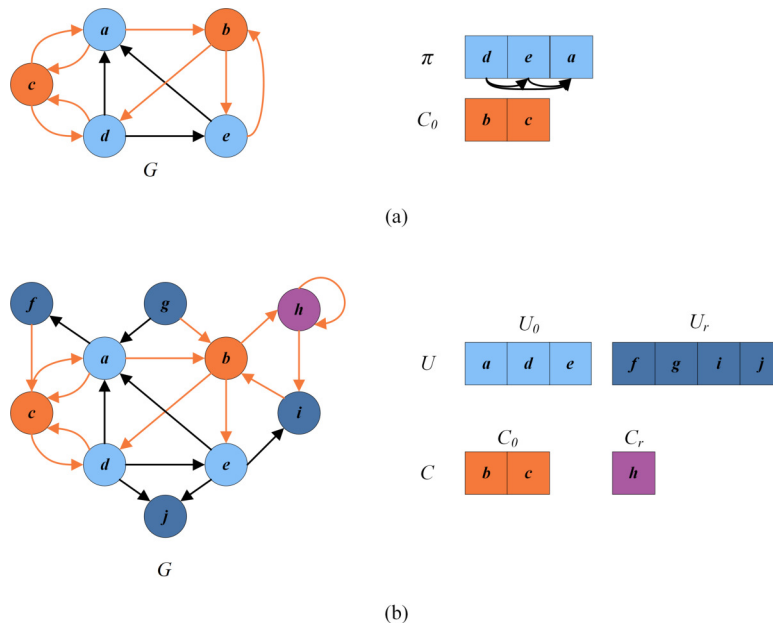

Figure 9. An example of recovery phase. (a) Feedback vertex set $C_0 = \{b, c\}$ for the reduced graph $G = (V_0, E_0)$; (b) Recovered feedback vertex set $C = \{b, c, h\}$.

3.7 Computational complexity and discussion

We consider first the greedy initialization procedure consisting of two stages. The first stage is to initialize the array $N_I(\pi)$, which can be realized in $O(|V_0|)$. The complexity of updating $N_I(\pi)$ is $O(d_{max}^2)$. The second stage is to construct the initial solution π , which is bounded by $O(|\pi| \times d_{max}^2)$, and $|\pi|$ is the size of π . Therefore, the time complexity of the greedy initialization procedure is $O(|V_0| + |\pi| \times d_{max}^2)$.

Next, the local search and perturbation procedures in the main loop of IDTS algorithm are considered. In each iteration of the local search, the dynamic threshold search and the descent search stages are performed alternately. The former is realized in $O(|\pi| \times d_{max} + |V_0|)$, and the latter in $O(|V_0|)$. Thus, the complexity of the local search procedure is $O(K_1 \times (|\pi| \times d_{max} + |V_0|))$, where K_1 is the number of iterations of the local search. Then, the perturbation procedure can be achieved in $O(|\pi| \times (\beta_1 + \beta_2 \times d_{max}^2))$, which is much smaller than that of the local search. Therefore, the complexity of one iteration of the main loop of IDTS algorithm is $O(K_1 \times (|\pi| \times d_{max} + |V_0|))$, and that of SA is $O(K_2 \times (d_{max}^2 + |V_0|))$, where K_2 is the number of iterations during each temperature period. Therefore, it can be seen that the two complexities are of the same order of magnitude.

4 EXPERIMENTAL RESULTS AND COMPARISONS

We test the proposed IDTS algorithm for the FVSP on 71 commonly-used benchmark instances in the literature and 30 large instances generated by this work (Section 4.1) and compare its results with the state-of-the-art algorithms in Section 4.3. In addition to these directed instances, we also present comparative results on directed graphs obtained by a slightly adapted version of the IDTS algorithm (Section 4.4). Below, we first present the 101 directed graphs as well as the experiment settings.

4.1 Benchmark instances

We use 101 benchmark instances, which are classified into five categories. No optimal solutions are known for the instances of the first to forth categories, while optimal solutions are known for the instances of the fifth category.

1. The first category consists of 40 instances that are randomly generated by Pardalos *et al.* using the FORTRAN random graph generator mkdigraph.f (Pardalos *et al.*, 1998)¹. The name of these instances is in the form of $P|V|-|E|^*$, where $|V| \in \{50, 100, 500, 1000\}$ is the number of vertices in the graph, and $|E| \in [100, 30000]$ is the number of edges. Given the number of vertices and edges, a graph is built by randomly selecting $|E|$ pairs of vertices as two endpoints of a directed edge. These instances are largely tested in the literature on the FVSP (Galinier *et al.*, 2013; Zhou, 2016).

2. The second category is composed of 10 random directed graphs, which are generated in the same way as the first category while the in-degree and out-degree of each vertex are no more than 10. These instances have $R|V|-|E|^*$ in their names. The number of vertices $|V|$ is in the interval $[100, 3000]$, and the number of edges $|E|$ in $[500, 15000]$.

3. The third category contains 10 artificially generated scale-free instances. These instances are generated by this work through the “powerlaw_cluster_graph” function of the “NetworkX” package, which is based on the algorithm proposed by Holme and Kim (2002). These instances are named as $S|V|-|E|^*$, where $|V|$ is in the interval $[500, 3000]$ and $|E|$ is in $[4900, 29900]$.

4. The fourth category is composed of 10 real-world instances from the Stanford large network dataset collection². Nine of these instances are snapshots of the Gnutella peer-to-peer file sharing network. The remaining instance is a temporal network representing Wikipedia users editing each other’s Talk page. The number of vertices $|V|$ is in the interval $[6301, 1140149]$, and the number of edges $|E|$ in $[20777, 7833140]$.

5. The fifth category is composed of the 31 classical (easy) ISCAS89 benchmark instances which are from digital sequential circuits (Brglez *et al.*, 1989). These instances have s^* in their names, where the number of vertices is in the range of $[3, 1728]$, and the number of edges in the range of $[4, 32774]$. These instances, whose optima are known, are largely tested in the literature on the FVSP (Levy and Low, 1988; Orenstein *et al.*, 1995; Lin and Jou, 1999).

4.2 Experiment settings

The IDTS algorithm is programmed in C++ and compiled by GNU g++ 4.1.2 with the -O3 flag. Experiments are carried out on a computer with an Intel(R) Core(TM)2 Duo CPU T7700 2.4GHz processor with 2GB RAM running Ubuntu CentOS Linux release 7.9.2009 (Core).

4.2.1 Parameters

The IDTS algorithm requires five parameters: the maximum non-improving iteration depth ω of local search, the tabu tenure tt , the first perturbation strength coefficient β_1 , the second perturbation strength coefficient β_2 and the thresholding coefficient δ . To tune these parameters, the “IRACE” package (López-Ibáñez *et al.*, 2016) was adopted to automatically recognize a group of appropriate values for 8 representative instances (with 50-30000 vertices), and its budget was set to 200 runs under a cutoff time described in Section 4.2.3. Table 1 presents both considered values and final tuned values of these parameters.

Table 1. Settings of important parameters.

Parameters	Section	Description	Considered value	Final value
ω	3.4	Search depth of the local search	{10,20,30,40,50,60,70}	20
tt	3.4.1	Tabu tenure	{1,2,3,4,5,6}	1
δ	3.4.1	Thresholding coefficient ($50 \leq V \leq 100$)	{1,2,3,4,5,6}	1
		Thresholding coefficient ($500 \leq V \leq 1000$)	{1,2,3,4,5,6}	4
		Thresholding coefficient ($1000 < V \leq 3000$)	{5,10,15,20,25,30}	10
		Thresholding coefficient ($3000 < V $)	{5,10,15,20,25,30}	20
β_1	3.5	The first perturbation strength coefficient	{0.02,0.04,0.06,0.08,0.1,0.2}	0.04
β_2	3.5	The second perturbation strength coefficient	{0.1,0.2,0.3,0.4,0.5,0.6}	0.3

¹<http://mauricio.resende.info/data/index.html>

²<http://snap.stanford.edu/data/>

These parameter values can be considered to form the default setting of the IDTS algorithm and were consistently used for our experiments to ensure a meaningful comparative study. By fine-tuning some parameters on an instance-by-instance basis, it would be possible to obtain better results.

4.2.2 Reference algorithms

Three state-of-the-art FVSP algorithms are adopted as reference methods to evaluate the IDTS algorithm for directed graphs.

- (1) Simulated annealing algorithm (SA) for the first category (Galinier et al., 2013);
- (2) Algorithm combining the reduction procedure and the simulated annealing algorithm (Red+SA) for the first category (Galinier et al., 2013), the re-implemented Red+SA (Re-Red+SA) for the categories two to five;
- (3) Belief propagation-guided decimation algorithm (BPD) (Zhou, 2016).

Among them, the codes of BPD were kindly provided by its author, and were run by us under the same experimental conditions as for the IDTS algorithm for a fair comparison. We also carefully re-implemented the Red+SA algorithm (Galinier et al., 2013), since its codes are unavailable. We used the re-implemented Red+SA algorithm (Re-Red+SA) to solve the instances of categories two to fifth and cited the results in Galinier et al. (2013) for the first category. Galinier et al. (2013) used a computer (Intel(R) Core(TM) 2 CPU T8300 2.4GHz with 2GB of RAM, which is comparable to our Intel computer running at 2.40GHz.

4.2.3 Stopping conditions

Cutoff time of each run. Reference algorithms BPD (Zhou, 2016) and SA (Galinier et al., 2013) have different stopping conditions. Thus, we adopted these average computation times as the cutoff times for our IDTS algorithm for fairness. Following Galinier et al. (2013), for the instances of the first category, the cutoff time is set to 0.03s to 0.07s for $n = 50$, 0.06s to 0.34s for $n = 100$, 1.8s to 5.2s for $n = 500$, 11s to 25.5s for $n = 1000$. For the second and third categories, the cutoff time is set to 1200s. For the fourth category, the cutoff time is set to 6000s for all compared algorithms. For the easy fifth category, the cutoff time is set to 15s.

Normal test. Following Galinier et al. (2013), we firstly ran our IDTS algorithm 30 times per instance with the above cutoff time.

Relaxed test. The SA algorithm (the Red+SA algorithm without the reduction procedure) (Galinier et al., 2013), was run 1000 times on each instance. Under this condition, it reported the currently best objective values for the benchmark instances of the first category. Like Galinier et al. (2013), we also ran IDTS 1000 times on each instance of the first category under the same stopping conditions.

4.3 Comparison with state-of-the-art results

4.3.1 Comparison of the results on the first-category instances

Table 2 displays the results of the Red+SA, BPD, and IDTS algorithms on the commonly-used 40 instances of the first category in the literature. The first 3 columns reveal the name, the number of vertices and the number of edges of each instance. Columns 4–7 provide the results of the Red+SA on each instance: the best objective value (Best) over 30 independent runs, the worst result (Worst), the average result (Avg), and the cutoff time (in seconds). Columns 8–15 report the results of the BPD and IDTS algorithm: the best, worst, average objective values and the average computation time (in seconds) to obtain the best result ($t(s)$). The last two columns (Δ_1 and Δ_2) indicate the difference between our best results (Best) and those of Red+SA and BPD (a negative value indicates an improved result). The row “p-value” is given to verify the statistical significance of the comparison between IDTS and the reference algorithms, which came from the non-parametric Friedman test applied to the best, worst and average values of IDTS and reference algorithms. A p-value less than 0.05 indicates a statistically significant difference.

Moreover, the rows #Better, #Equal, and #Worse indicate the number of instances for which Red+SA and BPD obtained a better, equal, and worse result compared to the IDTS algorithm for each performance indicator. The bold entries highlight the dominating results between the compared algorithms in terms of Best, Worst and Avg values.

We notice from Table 2 that IDTS performs satisfactorily and dominates the Red+SA algorithm by obtaining better results (Best) for 10 instances (see negative entries in column Δ_1) and equally-good results for the rest 30 instances. IDTS also gets better results in terms of the worst and average results. As

for BPD, in terms of the best results, IDTS obtains 16 better (see negative entries in column Δ_2) and 24 equal values; in terms of the worst and average results, IDTS obtains better values for all instances. The small p-values (< 0.05) confirm the statistical significance of the reported differences between IDTS and the reference algorithms.

In Galinier et al. (2013), SA (i.e., the Red+SA algorithm without the reduction procedure) reported several improved results over 1000 runs compared to the results of Red+SA in Table 2. Similarly, the IDTS algorithm was run 1000 times, and the comparative results of SA and IDTS are shown in Table 3, where the last column (Δ) shows the difference between the best results of IDTS (Best) and those of SA (a negative value indicates a better result). It reveals that IDTS further improves the results of SA and discovers 6 record-breaking results (indicated in bold) for the instances P500-2000, P500-2500, P1000-3000, P1000-3500, P1000-4000 and P1000-5000.

Table 2. Comparative results of IDTS with state-of-the-art algorithms on the 40 benchmark instances of the first category in normal test (30 independent runs).

Instance	V	E	Red+SA (Galinier et al., 2013)				BPD (Zhou, 2016)				IDTS				Δ_1	Δ_2
			Best	Worst	Avg	cutoff(s)	Best	Worst	Avg	t(s)	Best	Worst	Avg	t(s)

4.3.2 Comparison of the results on the second-category instances

Table 4 shows the comparative results between IDTS and the reference algorithms on the 10 instances of the second-category. In terms of the best results, IDTS dominates Re-Red+SA by obtaining better values for all instances, and BPD by obtaining 7 better, and 3 equal results. On the other hand, IDTS significantly outperforms Re-Red+SA and BPD in terms of the worst and average results by obtaining better or equal results for all instances (except for R3000-15000). The small p-values (< 0.05) indicate that there are significant differences between our best results and those of the two reference algorithms Re-Red+SA (p-value=1.60E-3) and BPD (p-value=8.20E-03).

Table 4. Comparative results of IDTS with state-of-the-art algorithms on the 10 benchmark instances of the second category in normal test (30 independent runs).

p-value			1.60E-03	1.60E-03	1.60E-03		8.20E-03	4.70E-03	1.14E-02							

Furthermore, Figure 10 summarizes the performance of the IDTS algorithm with that of the Re-Red+SA and BPD algorithms on these instances. Figure 10(a) presents the relationship between the number of vertices and the FVS size. Figure 10(b) shows the relationship between the number of vertices and the average computation time. One observes that the FVS size increases linearly while the average computation time increases exponentially with the increase of the number of vertices.

Figure 10. Comparisons of IDTS (in red) with BPD (in black) and SA (in blue). (a) The FVS size; (b) The average computation time.

4.3.3 Comparison of the results on the third-category instances

Table 5 presents the comparative results of IDTS with the reference algorithms Re-Red+SA and BPD for the instances of the third category. As shown in Table 5, IDTS outperforms Re-Red+SA by obtaining better results for all instances in terms of the best, worst and average results. Compared with BPD, IDTS obtains 7 better, 2 equal, and 1 worse values in terms of the best results; 7 better, 1 equal, and 2 worse values in terms of the worst results; 6 better, 1 equal, and 3 worse values in terms of the average results. Finally, the p-values smaller than 0.05 indicate IDTS significantly dominates each reference algorithm in terms of the best results.

4.3.4 Comparison of the results on the fourth-category instances

The comparative results of IDTS and the reference algorithms Re-Red+SA and BPD on the fourth category are summarized in Table 6. It can be seen that IDTS outperforms the reference algorithms for the instances

Table 5. Comparative results of IDTS with state-of-the-art algorithms on the 10 benchmark instances of the third category in normal test (30 independent runs).

Instance	V	E	Re-Red+SA				BPD (Zhou, 2016)				IDTS				Δ_1	Δ_2

of the fourth-category. Compared with Re-Red+SA, IDTS obtains 9 better and 1 equal results in terms of the best results, and better worst and average values for all instances. Compared with BPD, IDTS obtains 5 better, 4 equal, and 1 worse values in terms of the best results; 4 better, 1 equal and 5 worse values in terms of the worst and average results. The p-value of 2.70E-03 between IDTS and Re-Red+SA in terms of the best results indicate that there are significant differences between their results.

Table 6. Comparative results of IDTS with state-of-the-art algorithms on the 10 benchmark instances of the forth category in normal test (30 independent runs).

4.3.5 Results on the ISCAS89 benchmark instances

Table 7 shows the results of IDTS on the classical ISCAS89 benchmark instances. The instances with known optimal values were solved exactly by the branch and bound algorithm (H8WR) combined with eight reduction operations (Lin and Jou, 1999) and indicated by asterisks “*”. It can be observed that IDTS can easily reach the optimal solutions for these instances, while Re-Red+SA and BPD miss the 2 optimal solutions indicated in boldface.

4.4 Comparative results on undirected graphs

To make our IDTS algorithm applicable to undirected graphs, we modified the neighborhood condition that the number of conflicts equals 0 (as described in Section 2) to the constraint that for any vertex $v \in \pi$, there is at most one neighbor vertex $u \in \pi$ of v in front of v .

For our comparative study, we carefully re-implemented the SALS algorithm (Qin and Zhou, 2014) as its codes are unavailable. We regenerated 20 instances of the same characteristics using the generation method of Qin and Zhou (2014). These instances have ER* or RR* in their names, where the number of vertices is 100000, and the number of edges is in the range of [100000, 1000000]. The cutoff time is set to 6000s and both algorithms were run 30 times per instance.

Table 8 displays the results of the SALS and IDTS algorithms on the 20 regenerated instances. Columns 1-3 show the name, the number of vertices and the number of edges of each instance. Columns 4-11 respectively provide the results of the SALS and the IDTS on each instance: the best objective value (Best) over 30 independent runs, the worst result (Worst), the average result (Avg), and the average computation time (in seconds) to obtain the best result ($t(s)$). The last column (Δ) indicates the differences between our best results (Best) and those of SALS (a negative value indicates an improved result). The row “p-value” is given to verify the statistical significance of the comparison between IDTS and the reference algorithm, which came from the non-parametric Friedman test applied to the best, worst and average values of the two compared algorithms.

Table 7. Results of IDTS on the ISCAS89 benchmark instances.

#Worse			19	19	19						
p-value			1.31E-05	1.31E-05	1.31E-05						

The results indicate that our algorithm dominates the SALS algorithm (Qin and Zhou, 2014) by obtaining 19 better and 1 equal value in terms of the best, worst and average results. The small p-values (< 0.05) indicate that there are significant differences between our results and those of the reference algorithm SALS. This experiment demonstrates that the proposed algorithm is not only competitive for directed graphs, but performs very well for the undirected case of the problem as well.

5 ANALYSIS

This section conducts extra tests to analyze the advantages of two important components of the proposed IDTS algorithm: the thresholding coefficient and the perturbation strategy.

5.1 Effects of the thresholding coefficient

IDTS adopts the thresholding strategy illustrated in Section 3.4.1 to search both equivalent and better solutions. The oscillation between equivalent and better zones follows the increasing/decreasing of the thresholding coefficient δ (≥ 1) with an adjustment value. Thus, we analyze the effects of the thresholding coefficient by testing 5 candidate adjustment values: 1,2,3,4,5 for the instances with $|V| \leq 1000$ and 5,10,15,20,25 for the instances with $|V| > 1000$ (the higher the value, the larger the oscillation between equivalent and better solutions).

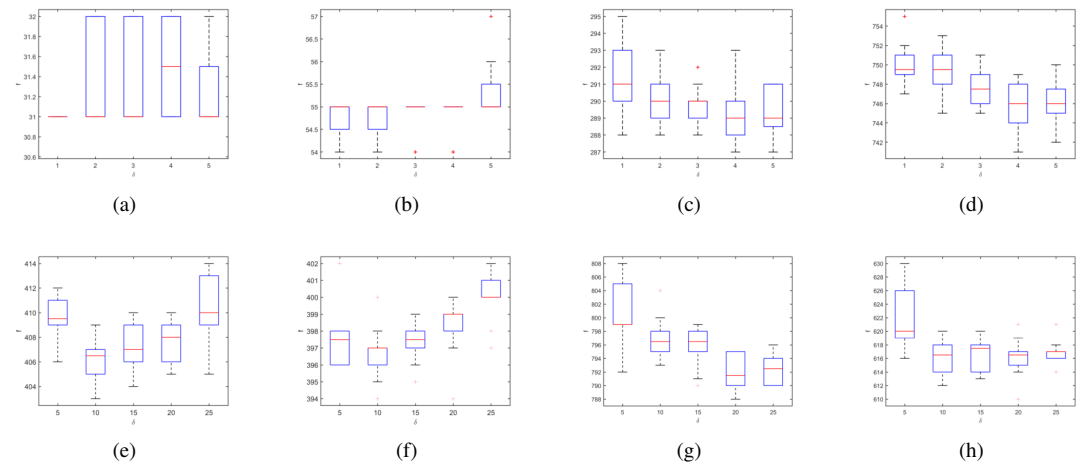

Figure 11. Effects of the increase/decrease value of the thresholding coefficient. (a) P50-600 (p-value = 1.68E-02); (b) P100-1100 (p-value = 9.37E-05); (c) P500-7000 (p-value = 2.71E-01); (d) P1000-30000 (p-value = 4.35E-05); (e) R1250-7500 (p-value = 4.53E-03); (f) S1250-12400 (p-value = 4.05E-04); (g) p2p-Gnutella24 (p-value = 1.37E-02); (h) p2p-Gnutella25 (p-value = 9.11E-01).

Figure 11 shows the Box and whisker plots of the results on 8 representative instances with different number of vertices. where the X-axis refers to the tested adjustment values and the Y-axis stands for the best objective values obtained. As a complement, we also calculate the p-values for each tested instance. Results are from 20 independent runs of each instance with a cutoff time as described in Section 4.2.3 per run. We observe that the adjustment values affect the performance of IDTS algorithm greatly for most instances except two instances (P500-7000 and p2p-Gnutella25). Moreover, then IDTS algorithm with the adjustment value 1 performs the best on instances with a number of vertices ($50 \leq |V| \leq 100$), with the adjustment value 4 on instances with a number of vertices ($500 \leq |V| \leq 1000$), with the adjustment value 10 on instances with a number of vertices ($1000 < |V| \leq 3000$), and with the adjustment value 20 on instances with a number of vertices ($|V| > 3000$). Finally, it is noted that the results of this experiment are consistent with the intuitive understanding that the higher the adjustment value, the more frequent the oscillation of the search between current configuration and new configuration. That is, large instances require large adjustment values to explore more new areas, while small instances require small adjustment values to fully explore each search area.

5.2 Effects of the perturbation operation

To evaluate the perturbation strategy of the proposed algorithm, we create 2 algorithmic variants (IDTS1 and IDTS2) where the perturbation strategy visits only feasible solutions. For IDTS, the perturbation first drops $\beta_1 \times |\pi|$ vertices with the highest move frequency, and then applies both DROP and INSERT moves to the next $\beta_2 \times |\pi|$ most frequently displaced vertices. For IDTS1, the perturbation strategy is disabled (i.e., by removing the line 7 in Algorithm 1). For IDTS2, the perturbation strategy only adopts the DROP move (by disabling lines 8-10 in Algorithm 6). 20 relatively difficult instances are selected as per the results provided in Tables 2-3, that is, their best results could not be achieved by all algorithms. We ran IDTS, IDTS1 and IDTS2 10 times to solve each selected instance under the same stopping conditions as before.

Table 9 displays the experimental results. The rows #Better, #Equal, and #Worse show the number of

instances for which IDTS1 and IDTS2 achieved a better, equal, or worse result than the IDTS algorithm for each performance indicator.

Even though both IDTS and IDTS1 obtain 10 equal results, the former can achieve 10 better results (against 0 for IDTS1). The small p-values (< 0.05) in terms of *Best* and *Avg* confirm that the reported differences between IDTS and IDTS1 were statistically significant. This experiment proves that the perturbation strategy adopted is an important way of diversification that makes the algorithm able to better explore the search space. Both IDTS and IDTS2 obtain 11 equal results while the former achieves 9 better results than the latter. The small p-value (< 0.05) indicates that IDTS is better than IDTS2. The above indicates that adopting DROP and INSERT operations in the perturbation procedure can enable the algorithm to reach a better performance.

6 CONCLUSIONS

An efficient stochastic local search algorithm IDTS was proposed to find the minimum set of feedback vertices in graphs. It begins with a low-complexity greedy initialization procedure, and alternates between a thresholding search stage and a descent stage. The IDTS algorithm has two innovative components, the solution-accepting strategy used in the thresholding search stage and the frequency-guided strategy in its perturbation procedure. The thresholding search stage involves an adjustable thresholding parameter δ that controls the search behavior and algorithm performance. Since fine-adjusting this parameter for a given problem instance can bring better solutions, it will be meaningful to study self-adaptive mechanisms to automatically adjust this parameter during the search.

Experimental evaluations on 101 diverse graphs proved the dominance of IDTS over the state-of-the-art SA (Galinier et al., 2013) and BPD (Zhou, 2016) algorithms. Particularly, it discovered 24 new best-known results (improved upper bounds), and reached the best-known or known optimal results of 75 other graphs. We also applied our algorithm to the case of undirected graph of the problem and showed its competitiveness against the SALS algorithm (Qin and Zhou, 2014). Besides, we conducted experiments to understand how each ingredient of IDTS (the thresholding and the short term learning-based perturbation) contributes to the algorithm performance.

Finally, it will be of interest to study the proposed framework for other critical vertex problems, such as the critical node detection (Bécsi and Gaskó, 2021) and finding the nodes with the highest betweenness-centrality scores (Mirakyan, 2021).
