## ABSTRACT

Annual increases in global energy consumption are an unavoidable consequence of a growing global economy and population. Among different sectors, the construction industry consumes an average of 20.1% of the world's total energy. Therefore, exploring methods for estimating the amount of energy used is critical. There are several approaches that have been developed to address this issue. The proposed methods are expected to contribute to energy savings as well as reduce the risks of global warming. There are diverse types of computational approaches to predicting energy use. These existing approaches belong to the statistics-based, engineering-based, and machine learning-based categories. Machine learning-based frameworks showed better performance compared to these other approaches. In our study, we proposed using Extreme Gradient Boosting (XGB), a tree-based ensemble learning algorithm, to tackle the issue. We used a dataset containing energy consumption hourly recorded in an office building in Shanghai, China, from January 1, 2015, to December 31, 2016. The experimental results demonstrated that the XGB model developed using both historical and date features worked better than those developed using only one type of feature. The best-performing model achieved RMSE and MAPE values of 109.00 and 0.24, respectively.

## INTRODUCTION

The annual rise in global energy use is one of the direct consequences of economic and population expansion. Energy use in the construction sector, which accounts for an average of 20.1% of the world's total energy use, is a vital aspect of the global energy consumption picture (Conti et al., 2016). In many nations, this proportion is substantially greater; for example, in China and the United States, it contributes up to 21.7% and 38.9% of total energy use, respectively (China Association of Building Energy Efficiency, 2021; Becerik-Gerber et al., 2014). This rising energy use worsens global warming and causes natural resource depletion. Therefore, increasing the efficient use of energy in the construction sector is essential because it lessens the risk of global warming and enhances sustainable growth. To effectively manage diverse technical activities (e.g., demand response during construction (Dawood, 2019), organization of urban power systems (Moghadam et al., 2017), and defect detection (Kim et al., 2019), prediction of energy demand is crucial in preventing ineffective energy use in many sectors (Min et al., 2023; Li et al., 2022), especially construction (Liu et al., 2023; Zhang et al., 2021). Besides, a good estimation of energy demand helps to create energy-saving plans for heating, ventilation, and air conditioning (HVAC) systems (Du et al., 2021; Min et al., 2019). To address this issue, several computation frameworks were proposed to predict energy use. Zhao and Magoulès (2012) performed a comprehensive review of numerous computational frameworks developed to estimate construction energy use. According to their investigation, all approaches for predicting energy use may be generally categorized into three groups: statistics-based, engineering-based, and machine learning-based techniques.

Statistics-based approaches were employed to model the correlation between energy use and involved attributes with a parametrically defined mathematical formula. Ma et al. (2010) developed models using multiple linear regression and self-regression techniques and essential energy consumption features

47 characterized by particular population activities and weather conditions. The least squares method was  
48 used to estimate parameters as well as approximate monthly energy consumption for broad-scale public  
49 housing facilities (Ma et al., 2010). Conducting the principal component analysis, Lam et al. (2010)  
50 discovered three significant climatic variables, comprising dry-bulb temperature, wet-bulb temperature,  
51 and global solar radiation, to create a novel climatic index. After that, regression models were built  
52 to establish an association focusing on the daily period between the climatic index and the simulated  
53 cooling demand. Despite fast and simple calculations, these approaches often lack flexibility and have  
54 poor prediction ability due to limitations in handling stochastic occupant behaviors and complicated factor  
55 interactions between factors (Ahmad et al., 2014).

56 Applying physics' concepts and thermodynamic calculations, engineering-based approaches determine  
57 the energy use of each building component (Zhao and Magoulès, 2012). Although the defined relationships  
58 between input and output variables improve the model's explainability, these approaches need curated  
59 sources of building and environmental data whose accessibility is very limited (Zhao and Magoulès, 2012).  
60 Some researchers have attempted to reduce the complexity of engineering models in order to improve their  
61 ability to accurately predict energy use. Yao and Steemers (2005) developed a straightforward approach  
62 for generating a load profile (SMLP) to predict the breakdown of everyday energy consumed by electrical  
63 household appliances. This technique estimated seasonal energy demand since the average daily energy  
64 (consumed by these appliances) seasonally fluctuated. Based on frequency response characteristic analysis,  
65 Wang and Xu (2006) obtained simple physical properties to determine the model parameters. In addition,  
66 they used monitored operating data to identify parameters for a thermal network of lumped thermal mass  
67 to describe a building's interior mass (Wang and Xu, 2006). The prediction accuracy, however, is one of  
68 the most concerning issues because the simplified model may be somewhat underfitting (Wei et al., 2018).

69 Machine learning-based approaches utilize either traditional machine learning (e.g., Random Forest,  
70 Support Vector Machines) or deep learning (e.g., Artificial Neural Networks (ANN), Convolutional Neural  
71 Networks (CNN), recurrent neural networks (RNN)) for modeling by learning from historical data (Nora  
72 and El-Gohary, 2018; Tian et al., 2019). These machine learning-based approaches usually exhibit better  
73 performance compared to other methods, especially in event detection (Wang et al., 2023; Sun et al.,  
74 2023c; Ren et al., 2022) and other applications using time-series data (Sun et al., 2023a,b; Long et al.,  
75 2023). To predict perennial energy use, Azadeh et al. (2008) suggested using ANN in combination with  
76 an analysis of variance. The approach was demonstrated to outperform the standard regression model.  
77 Hou and Lian (2009) developed a computational framework using support vector machines to estimate the  
78 cooling demand of an HVAC system, and their findings showed that it was dominant over Autoregressive  
79 Integrated Moving Average (ARIMA) models. Tso and Yau (2007) used Decision Tree (DT), stepwise  
80 regression, and ANN to estimate Hong Kong's power consumption. The results suggested that the DT  
81 and ANN techniques performed somewhat better during the summer and winter seasons, respectively.  
82 However, many traditional machine learning approaches use shallow frameworks for modeling, reducing  
83 prediction efficiency. As black box models, deep neural networks do not well explain physical behaviors,  
84 but they can effectively learn abstract features from raw inputs to build superior models (Ozcan et al.,  
85 2021a). Cai et al. (2019) constructed prediction frameworks using RNN and CNN to measure time-series  
86 building-level load in recursive and direct multi-step approaches, respectively. Compared to the seasonal  
87 ARIMA model with exogenous inputs, the gated 24-hour CNN model had its prediction accuracy improved  
88 by 22.6% in the experiments. To calculate electric load consumption, Ozcan et al. (2021b) suggested  
89 dual-stage attention-based recurrent neural networks consisting of encoders and decoders. Experimental  
90 results revealed that their proposed method vanquished other methods (Ozcan et al., 2021b). A hybrid  
91 sub-category of deep learning called deep reinforcement learning (DRL) blends reinforcement learning  
92 decision-making with neural networks (Mnih et al., 2015; Levine et al., 2016; Sallab et al., 2017). DRL  
93 approaches are often used in the construction industry to investigate the ideal HVAC control (Wei et al.,  
94 2017; Huang et al., 2020). DRL approaches obtained promising outcomes for energy use prediction (Wei  
95 et al., 2017; Huang et al., 2020). Liu et al. (2020) examined the efficacy of DRL approaches for estimating  
96 energy consumption, and their results suggested that the deep deterministic policy gradient (DDPG)  
97 method had the most predictive power for single-step-ahead prediction. Although the deployment of DRL  
98 approaches yields initial success, further research is required to determine its ability to solve this issue.

99 In this study, we proposed a more effective method to predict energy use in the construction sector  
100 using four tree-based machine learning algorithms, including Random Forest (RF), Extremely Randomized  
101 Trees (ERT), Extreme Gradient Boosting (XGB), and Gradient Boosting (GB). Four feature sets are

102 created to combine with four learning algorithms to form 16 models. The four feature sets correspond to  
 103 four development and testing scenarios: (1) using 1-3 historical hours, (2) using 1-5 historical hours, (3)  
 104 using 1-7 historical hours, and (4) using 1-9 historical hours before prediction time as input features. The  
 105 best-performing models are then selected as the final models for evaluation.

## 106 MATERIALS AND METHODS

### 107 Dataset

108 In this study, we used an energy consumption dataset recorded in an office building in Shanghai (Fu et al.,  
 109 2022). The energy consumption data were recorded hourly from January 1, 2015, to December 31, 2016.  
 110 Since data from February 29, 2016 was not recorded, the dataset has a total of 17,520 recorded samples.  
 111 The original dataset was split into three parts: ‘From 1 January 2015 to 30 April 2016’, ‘From 1 May  
 112 2016 to 31 August 2016’, and ‘From 1 September 2016 to 31 December 2016’ which were used as a  
 113 training set, validation set, and test set. In the case of time series data, random samples might lead to a  
 114 failed training session since the model could not learn the data that were included in the validation or test  
 115 set. The information about the data sets is summarized in Table 1.

Dataset	No. of samples	Time period
Training	13872	From 3 January 2015 to 3 August 2016
Validation	1440	From 4 August 2016 to 2 October 2016
Test	2160	From 3 October 2016 to 31 December 2016
<b>Total</b>	<b>17472</b>	<b>From 1 January 2015 to 31 December 2016</b>

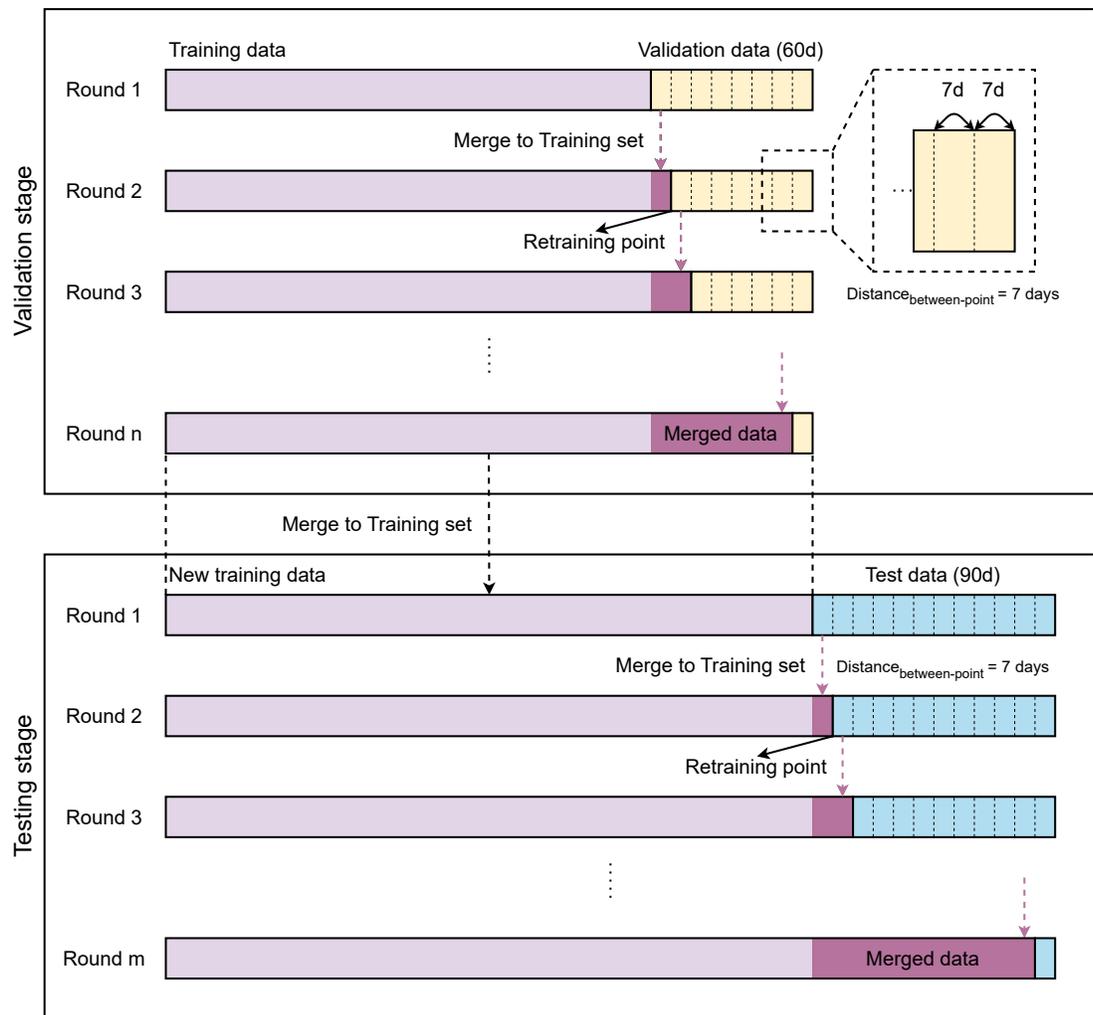

Table 1. Data for model development and evaluation

### 116 Overview of Method

117 Figure 1 provides a flowchart of the modeling strategies of our work with two stages: validation and  
 118 testing. The validation stage aims to select the best model, while the testing stage focuses on evaluating  
 119 the performance of the selected one. The modeling steps of both stages are similarly designed. As the  
 120 samples are time-series, training, validation, and test data are partitioned in time-sequential order. The  
 121 validation and test sets contain 1440 and 2160 samples, which correspond to 60 and 90 days, respectively.  
 122 Initially, the model is developed with the training data and then evaluated on a timely ordered list of 7  
 123 sub-validation sets before being retrained. Each sub-validation set contains 336 validation samples, which  
 124 are equivalent to 14 days. After 7 days, the model is retrained with an updated training set, which is a  
 125 combination of previous training samples and 7-day validation samples. This process is repeated until no  
 126 validation samples are left. After completing the validation stage, we compare the performance of these  
 127 models to select the best one. The best model is then retrained with the new training set, which contains  
 128 all training and validation samples. The obtained model is finally evaluated on the test data in the same  
 129 manner as in the validation stages.

### 130 Data Processing and Featurization

131 Figure 2 describes the main steps in data sampling, processing, and featurization. After obtaining the  
 132 training, validation, and test sets, we processed the data to generate their feature sets. The original data  
 133 frame has only two columns: ‘recorded time’ and ‘energy used’. We created two types of features,  
 134 including *historical feature* (Figure 2.B) and *date feature* (Figure 2.C). The historical features are energy  
 135 values that were recorded 1, 2, ...,  $n$  hours before the prediction time with  $n = 48$  (2 days). The label <sub>$i$</sub>   
 136 (value of energy used) of sample <sub>$i$</sub>  is filled to the column ordered 48<sup>th</sup> of sample <sub>$i+1$</sub> . The columns ordered  
 137 48<sup>th</sup>, 47<sup>th</sup>, 46<sup>th</sup>, ..., 1<sup>st</sup> present the recorded values of energy used before 1, 2, 3, ..., 48 hours, respectively.  
 138 The first sample was recorded on ‘January 1, 2015 at 00’ hour with undetermined historical features. The  
 139 next 47 samples have their historical features determined with 1, 2, 3, ..., 47 recorded values. Since the first  
 140 48 samples have historical features containing undetermined values, we removed them from the dataset.  
 141 The samples recorded after ‘January 3, 2015 at 00 hour’ have the historical features of all determined  
 142 values. The date features of a sample give information on ‘day of year’, ‘whether it is a holiday’, and  
 143 ‘when it is recorded’. The historical and date features are expressed as 48-dimensional and 3-dimensional  
 144 numeric vectors, respectively. To select the best feature set, we examined three scenarios, including using  
 145 only historical features, using only date features, and using combinatory features (Table 2).

**Figure 1.** Overview of Method.

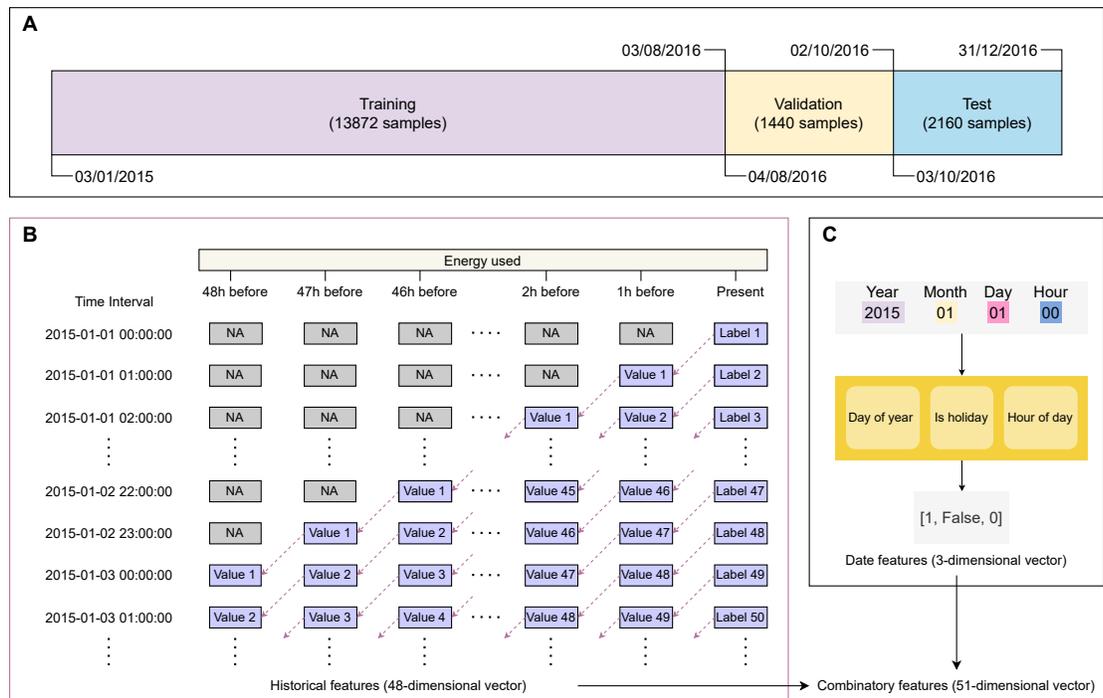

Scenario	No. of features	Annotation
1	48	Using 1,2, ..., 48 hours before prediction time as historical features
2	3	Using day of year, holiday information, and recorded hour as date features
3	51	Using both historical features and date features as combinatory features

**Table 2.** Scenarios for model development and evaluation.

## 146 Machine Learning Algorithms

### 147 *Random Forest*

148 Random Forest (RF) (Breiman, 2001) is a supervised machine learning method that utilizes an ensemble  
 149 of decision trees. It was developed based on the “bagging” concept (Breiman, 1996) and the use of random  
 150 feature selection (Ho, 1995), which allows for the creation of multiple decision trees that are distinct  
 151 from one another. In RF, the output is determined by either the mode of the classes or the average of the  
 152 predicted values of the multiple trees, depending on the task at hand (i.e., classification or regression). One  
 153 of the key benefits of RF is its ability to overcome the issue of overfitting, which is a common problem in  
 154 decision tree algorithms. Overfitting occurs when a model becomes too closely fitted to the training data,  
 155 leading to poor generalization to unseen data. RF is able to mitigate this issue due to its use of multiple  
 156 decision trees and the random feature selection process.

**Figure 2.** Major steps in data sampling, processing, and featurization. (A. Data sampling, B. Creating historical variables, C. Extracting binary timing vectors)

### 157 **Extremely Randomized Trees**

158 Extremely Randomized Trees (ERT) (Geurts et al., 2006) is a supervised machine learning method that is  
 159 designed to address both classification and regression tasks. It is based on the principles of tree-based  
 160 ensembles, and the central aspect of this method is the significant randomization of both the attributes and  
 161 the cut points used to divide a tree node. In some cases, ERT may construct trees whose structures are  
 162 entirely random and unrelated to the output values of the training sample. The degree of randomization  
 163 can be controlled through the use of a parameter, allowing the user to adjust the intensity of randomization  
 164 as needed. ERT is known for its accuracy as well as its improved computational speed compared to other  
 165 tree-based methods such as Random Forest.

### 166 **Extreme Gradient Boosting**

167 eXtreme Gradient Boosting (XGB) (Chen and Guestrin, 2016) is a powerful supervised machine learning  
 168 algorithm that combines the principles of Gradient Tree Boosting (Friedman, 2001; Mason et al., 2000)  
 169 with Classification and Regression Trees (CART) (Steinberg and Colla, 2009). It is equipped with  
 170 additional regularization options, including L1 and L2 penalization. XGB is trained to minimize a  
 171 regularized objective function that includes a convex loss function and a penalty scoring function based  
 172 on the difference between the predicted outcomes and the true labels. Its boosting strategy involves the  
 173 successive use of random subsets of data and features, with the weight of mispredicted classes increasing  
 174 in each iteration. This method has been shown to be effective for a range of tasks.

### 175 **Gradient Boosting**

176 Gradient Boosting (GB) (Friedman, 2001, 2002) is a supervised machine learning technique that is based  
 177 on the concept of improving the performance of a weak learner through the use of an ensemble approach.  
 178 It involves sequentially training weak learners on filtered subsets of the data, with each successive learner  
 179 focusing on the observations that were not well predicted by the previous learners. GB can be applied to a  
 180 variety of tasks, including regression, multi-class classification, and other problems, by utilizing arbitrary  
 181 differentiable loss functions. It is a flexible method that can be generalized to a wide range of situations.

### 182 **Model Selection**

183 To select the best-performing model for testing, we validated 12 models (created by four learning  
184 algorithms in combination with three feature sets). Since all models were developed using tree-based  
185 algorithms, data normalization can be bypassed. The parameter `max_depth` was used for model tuning,  
186 while the other parameters were set to default once the best model was selected. The model was selected  
187 based on mean absolute percentage error (MAPE) and root mean squared error (RMSE).

## 188 **RESULTS AND DISCUSSION**

189 The model's performance was evaluated using two metrics: root mean squared error (RMSE) and mean  
190 absolute percentage error (MAPE).

$$\text{RMSE} = \sqrt{\sum_{i=1}^N \frac{(\hat{y}_i - y_i)^2}{n}}, \quad (1)$$

$$\text{MAPE} = \frac{1}{n} \sum_{i=1}^N \left| \frac{A_i - F_i}{A_i} \right|, \quad (2)$$

191 where  $n$  is the number of samples,  $\hat{y}$  is the predicted value, and  $y$  is the true value.

### 192 **Model Validation**

193 Table 3 provides a comparative analysis of the performance of the 12 developed models on the validation  
194 set. Generally, models developed using combinatory features obtain better performances, followed by  
195 those developed with historical features and those developed with date features only. The GB model  
196 shows better performance than other models in scenario 2, with the smallest RMSE and MAPE values.  
197 While in scenarios 1 and 3, the XGB models work more effectively compared to the others, the ERT  
198 models have limited performance in all scenarios in terms of RMSE and MAPE. The GB models are  
199 ranked as the second-best models in scenarios 2 and 3. The performance of RF models is not competitive  
200 in all scenarios. The results are not surprising because the RF and ERT algorithms share more common  
201 characteristics, while the XGB algorithm is developed based on the concept of the GB algorithm. Based  
202 on the results, we selected the XGB model developed using combinatory features as our final model for  
203 evaluation (Table 4).

Scenario	Model	Metric	
		RMSE	MAPE
1	RF	227.76	0.50
	ERT	364.06	0.96
	XGB	238.02	0.47
	GB	264.72	0.57
2	RF	311.39	0.78
	ERT	322.48	0.70
	XGB	309.35	0.72
	GB	277.25	0.53
3	RF	245.76	0.28
	ERT	186.54	0.37
	XGB	133.56	0.21
	GB	150.41	0.25

**Table 3.** Performance of the 12 models on the validation set.

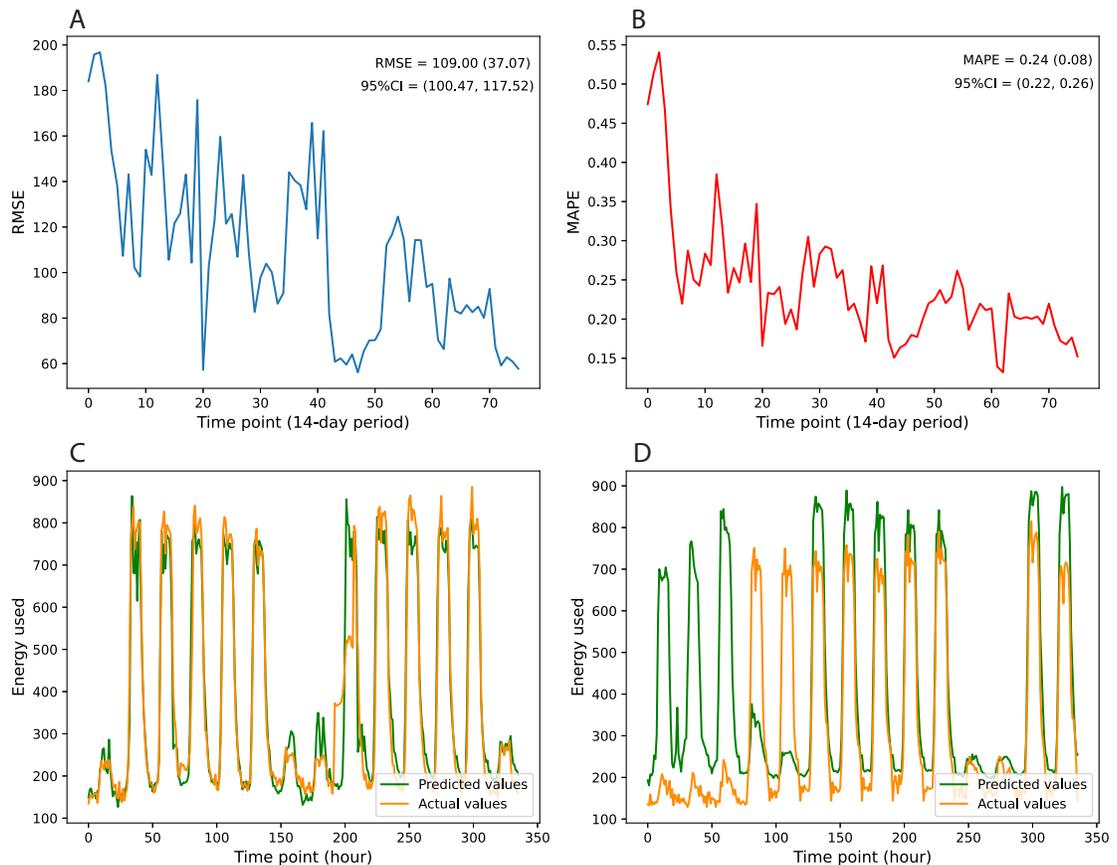

### 204 **Model Evaluation**

205 Figure 3 gives information on the variation of prediction error over multiple time points of test data. The  
206 results indicate that the prediction errors show downward trends over the testing period. The errors tend

Parameter (max_depth)	Metric	
	RMSE	MAPE
2	146.87	0.32
3	112.38	0.20
4	124.3	0.21
5	135.29	0.21

**Table 4.** Performance of the tuned XGB models on the validation set.

207 to increase when the time point's distance to the retraining point is large and then immediately drop  
 208 once we retrain the model with updated training data. Figures 3.A and B visualize the changes in RMSE  
 209 and MAPE over 76 time points, where each time point represents the 14-day period with between-point  
 210 distances of one day. Besides, Figures 3.C and D illustrate the performance of the best and worst predicted  
 211 time points over 336 consecutive hours. To quantify the variation of prediction error, we computed the  
 212 mean, standard deviation, and 95% confidence interval (95% CI). The RMSE achieves a mean of 109.00  
 213 and a standard deviation of 37.07, while the MAPE obtains a mean of 0.24 and a standard deviation  
 214 of 0.08. The 95% CI values of RMSE and MAPE are (100.47, 117.52) and (0.22, 0.26), respectively  
 215 (Table 5).

**Figure 3.** Variation in prediction error over multiple time points of test data (A. MAPE, B. RMSE, C. Best predicted time point, D. Worst predicted time point).

## 216 CONCLUSIONS

217 The experimental results confirm the robustness and effectiveness of machine learning, especially Extreme  
 218 Gradient Boosting (XGB), in developing computational models predicting energy use. The achieved

Metric	Statistics		
	Mean	Standard deviation	95% Confidence Interval
RMSE	109.00	37.07	(100.47, 117.52)
MAPE	0.24	0.08	(0.22, 0.26)

**Table 5.** The statistical values of metrics on the test set.

219 results indicate that the XGB models work more effectively than other tree-based models to address this  
220 issue. Also, the selection of a suitable historical period is essential to improving model performance.
