Fuzzing has become an important method for finding vulnerabilities in software. For fuzzing programs expecting structural inputs, syntactic- and semantic-aware fuzzing approaches have been particularly proposed. However, they still cannot fuzz in-memory data stores sufficiently, since some code paths are only executed when the required data are available. In this paper, we propose a Data-Aware Fuzzing method, DAFuzz, which is designed by considering the data used during fuzzing. Specifically, to ensure different data-sensitive code paths are exercised, DAFuzz first loads different kinds of data into the stores before feeding fuzzing inputs. Then, when generating inputs, DAFuzz ensures the generated inputs are not only syntactically and semantically valid but also use the data correctly. We implement a prototype of DAFuzz based on Superior and use it to fuzz *Redis* and *Memcached*. Experiments show that DAFuzz covers 13%~95% more edges than AFL, Superior, AFL++, and AFLNet, and discovers vulnerabilities over 2.7x faster. In total, we discovered 4 new vulnerabilities in *Redis* and *Memcached*. All the vulnerabilities were reported to developers and have been acknowledged and fixed.

DAFuzz: Data-aware Fuzzing of In-Memory Data Stores

ABSTRACT

Fuzzing has become an important method for finding vulnerabilities in software. For fuzzing programs expecting structural inputs, syntactic- and semantic-aware fuzzing approaches have been particularly proposed. However, they still cannot fuzz in-memory data stores sufficiently, since some code paths are only executed when the required data are available. In this paper, we propose a Data-Aware Fuzzing method, DAFuzz, which is designed by considering the data used during fuzzing. Specifically, to ensure different data-sensitive code paths are exercised, DAFuzz first loads different kinds of data into the stores before feeding fuzzing inputs. Then, when generating inputs, DAFuzz ensures the generated inputs are not only syntactically and semantically valid but also use the data correctly. We implement a prototype of DAFuzz based on Superion and use it to fuzz `Redis` and `Memcached`. Experiments show that DAFuzz covers 13%~95% more edges than AFL, Superion, AFL++, and AFLNET, and discovers vulnerabilities over 2.7× faster. In total, we discovered 4 new vulnerabilities in `Redis` and `Memcached`. All the vulnerabilities were reported to developers and have been acknowledged and fixed.

1 INTRODUCTION

Fuzzing has become an important way to find vulnerabilities in software (Manes et al., 2019; Zhu et al., 2022), and coverage-guided fuzzing (CGF) (Zalewski, 2017; Böhme et al., 2016) is one of the most popular fuzzing technologies, since it could gradually explore the state space of the program under test (PUT) even if only several initial seeds are given. This is because when it mutates seeds to create new inputs, it traces the coverage information of the new inputs, and adds the inputs into the seed pool as new seeds if the inputs have new code coverage. CGF fuzzers (e.g., AFL (Zalewski, 2017), honggfuzz (Hon, 2023), libFuzzer (lib, 2023), and AFL++ (Fioraldi et al., 2020)) are the main fuzzers used in the famous OSS-Fuzz project (Google Security Team, 2018), which has discovered over 8,900 vulnerabilities and 28,000 bugs across 850 open-source projects by February 2023¹. CGF fuzzers have also been used to discover vulnerabilities in other fields including operation systems (Google, 2015; Pan et al., 2021), network protocols (Pham et al., 2020; Ba et al., 2022), as well as Internet of Things (IoT) (Zheng et al., 2019; Zeng et al., 2020).

It is known to be difficult for CGF fuzzers to fuzz programs expecting structural inputs because it is hard to get syntactically and semantically valid inputs through seed mutation (Wang et al., 2019). To tackle the problem, grammar-aware CGF fuzzers that understand the grammar (syntax and semantics) of inputs have been proposed recently (Wang et al., 2019; Han et al., 2019; Padhye et al., 2018; Park et al., 2020; He et al., 2021). They usually consider syntactic and semantic constraints when creating new inputs, and then the created new inputs could pass the corresponding syntax and semantics checks in the code.

In-memory data stores like `Redis` are widely used in thousands of companies like Twitter and Snapchat², since they provide very efficient and convenient access to data, and it is important to discover

¹<https://github.com/google/oss-fuzz>

²<https://redis.io/docs/about/users/>

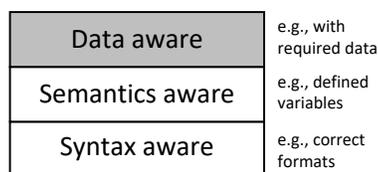

Figure 1. DAFuzz considers the syntax, semantics, and data (which is a newly proposed factor) at the same time in fuzzing.

any vulnerabilities in them timely. However, when fuzzing in-memory data stores with CGF fuzzers, only considering the syntactic and semantic validity of the inputs is not enough. In-memory data stores usually use different commands with defined parameter formats to access the data, and may use serialization protocols for communicating between their clients and servers. However, even if commands are sent in syntactically and semantically format, some code paths may not be executed when the required data are not available. This is because the statuses of the data directly control how commands are processed and which code paths are executed. For example, the processing of command “RPOP *key*” in *Redis* may execute a quick-exit code path and return an empty array when the list *key* is empty, and may execute a popping data code path and return the last element of the list only when the list *key* is not empty.

In this paper, we propose DAFuzz, a data-aware fuzzing method for in-memory data stores that considers data requirements in addition to syntactic and semantic validity in fuzzing, as shown in Figure 1. First, DAFuzz designs a data construction algorithm to generate a special data set which is used to satisfy the requirements of different code paths. Then, DAFuzz generates inputs according to the data set, as well as the grammar of commands. Finally, DAFuzz also uses syntax-aware mutation to improve mutation efficiency. We implement a prototype of DAFuzz based on Superion (Wang et al., 2019) (a syntax-aware fuzzer based on AFL (Zalewski, 2017)), and test DAFuzz with two popular in-memory data stores *Redis* and *Memcached*. The experiments show that DAFuzz could find 13%~95% more edges than AFL, Superion, AFL++ (Fioraldi et al., 2020), and AFLNET (Pham et al., 2020), and discover the same number of edges at least 19× faster. In addition, DAFuzz finds the same vulnerabilities as other fuzzers but finds them at least 2.7× faster. All 4 vulnerabilities (3 in *Redis* and 1 in *Memcached*) were reported to developers and have been fixed in new releases.

In summary, this paper contains the following contributions.

- We propose the first data-aware fuzzing method for reaching code paths that are executed only when the required data are available.
- We design an algorithm to construct a data set to load for fuzzing, and an algorithm to generate fuzzing inputs that use the required data and are syntactically and semantically valid as well.
- We implement a prototype of DAFuzz based on Superion, and compare DAFuzz with other state-of-the-art fuzzers including AFL, Superion, AFL++, and AFLNET using two popular in-memory data stores *Redis* and *Memcached*. We discover 4 new vulnerabilities and report them to developers. We share the DAFuzz prototype as Free and Open Source Software at <https://github.com/hdusoftsec/DAFuzz> (release after publication).

2 BACKGROUND AND MOTIVATING EXAMPLE

2.1 Background

In-memory data store. In-memory data stores like *Redis* and *Memcached* are widely used in web and mobile application servers. They are popular because they store data in *memory* and provide very efficient and convenient access to the data, which makes them quite suitable for tasks like caching and session management. In-memory data stores may support different kinds of data types, for example, *Redis* supports *string*, *list*, *set*, *sorted set*, *hash*, etc³. They usually use different commands with defined parameter formats to access data. For example, in *Redis* “SET *key value*” is for storing *value* to *key*, and both *value* and *key* could be arbitrary strings. They may also use some serialization protocols (i.e., application layer network protocols) for client-server communication (i.e., for sending and receiving

³<https://redis.io/docs/data-types/tutorial/>

86 commands and data). For example, `Redis` mainly uses RESP (REdis Serialization Protocol) protocol
87 ⁴ for client-server communication. It is important to eliminate any vulnerabilities in such widely used
88 programs, especially since they usually run on servers that have rich computation and network resources.

89 **Fuzzing.** Fuzzing has been developed for over thirty years (Miller et al., 1990), and coverage-guided
90 fuzzing (CGF) now probably is the most popular fuzzing technology (Manes et al., 2019; Zhu et al.,
91 2022). CGF fuzzer usually first instruments the PUT to trace coverage information when running each
92 input, and starts a fuzzing loop with some initial seeds. In the fuzzing loop, it keeps selecting seeds and
93 mutating them to create new inputs and runs the inputs with the PUT. The mutation of a seed may include
94 a deterministic stage in which the seed is sequentially changed by predefined steps like one-by-one bit
95 flipping, and an indeterministic (havoc/splicing) stage in which the seed is applied with stacking changes
96 and may be spliced with another randomly selected seed first. If any new inputs have new code coverage,
97 they are added to the seed pool as new seeds. Thus, the fuzzer could gradually explore more state space
98 of the PUT, compared to traditional unit testing and mutation testing.

99 Mutation-based CGF fuzzers do not perform well for programs expecting structural inputs, such
100 as Javascript engines, XML parsers, etc., because it is hard for the fuzzers to get syntactically and
101 semantically valid inputs during random seed mutation (Wang et al., 2019). Programs expecting structural
102 inputs usually have syntax and semantics checks early in the program execution, and inputs that are either
103 not syntactically or semantically valid could not pass such checks to execute deep program code paths.
104 Syntax-aware (Wang et al., 2019; Padhye et al., 2018) and semantics-aware fuzzers (Han et al., 2019; He
105 et al., 2021) have been proposed to solve the problem. They understand the grammar of inputs and could
106 obtain new inputs that are syntactically and even semantically valid. For example, they may convert seeds
107 into abstract syntax trees (ASTs) and mutate at the AST tree node level instead of the byte level of seeds
108 (Wang et al., 2019).

109 2.2 Motivating Example

110 Only syntax-aware and semantics-aware fuzzing is not enough for efficiently fuzzing in-memory data
111 stores like `Redis`, since some code paths could only be executed when the required data are available.
112 Take the processing of `RPOP key` command in `Redis` for example. The command is to remove and return
113 the last element of the `key` list, and its corresponding code snippet in `tl_list.c` is shown in Figure 2a.
114 An input “`RPOP list1`” is both syntactically valid (i.e., command format) and semantically valid (i.e.,
115 using `list1` without declaration first is correct in `Redis`), however, if `list1` is empty, the execution exits
116 at line 5 and the left code lines in the function are not executed. Another example is the processing of
117 `SINTER key [key ...]` command. The command is to return the intersection of all the given sets, and its
118 code snippet in `tl_set.c` is shown in Figure 2b. The execution would end early at line 6 if any set is
119 empty, and even if they are all not empty, the code lines represented between line 16 and line 18 are not
120 executed if the intersection of the sets is empty.

121 3 DAFUZZ APPROACH

122 3.1 Overview

123 DAFuzz incorporates data-aware fuzzing, in addition to syntax-aware and semantics-aware fuzzing.
124 The architecture of DAFuzz is shown in Figure 3, and its differences from other fuzzers like AFL are
125 highlighted. First, DAFuzz uses a data construction module to produce the data that would be used later
126 in program execution and input generation in the fuzzing loop (Section 3.2). Second, in the fuzzing
127 loop, DAFuzz uses a data-aware and semantics-aware generation module for generating inputs that
128 are syntactically and semantically valid, as well as referring to valid data (Section 3.3). Last but not
129 least, DAFuzz uses syntax-aware mutation in the fuzzing loop for creating syntactically valid inputs
130 (Section 3.4).

131 The fuzzing loop of DAFuzz is shown in Algorithm 1, and its differences from AFL are highlighted
132 as well. DAFuzz is still a CGF fuzzer like AFL, i.e., with a fuzzing loop that keeps choosing a seed,
133 mutating it to get inputs, and fuzzing inputs by feeding them to the PUT. However, in the fuzzing loop, it
134 uses input generation as well for using the grammar and the data constructed. Using input generation
135 together with seed mutation to create inputs is similar to some CGF fuzzers like `syzkaller` (Google, 2015).

```

1. void sinterGenericCommand(client *c, robj **setkeys, ...) {
2.     /* Check empty set */
3.     ...
4.     if (empty > 0) {
5.         ...
6.         return;
7.     }
8.     /* Compute the intersection set */
9.     ...
10.    if (cardinality_only) {
11.        addReplyLongLong(c,cardinality);
12.    } else if (dstkey) {
13.        /* Store the resulting set into the target, if the
14.         * intersection is not an empty set. */
15.        if (setTypeSize(dstset) > 0) {
16.            setKey(c,c->db,dstkey,dstset,0);
17.            addReplyLongLong(c,setTypeSize(dstset));
18.            ...
19.        } else {
20.            ...
21.        }
22.    }
23. }
24. ...
25. }

```

(b) The SINTER command.

Figure 2. Code snippets for processing two commands in Redis.**Figure 3.** The DAFuzz architecture, with differences from AFL highlighted.

Algorithm 1 The DAFuzz fuzzing loop. The differences between DAFUZZ and AFL are highlighted in grey.

Input: Initial seed set s , grammar G , data set D

- 1: **repeat**
- 2: generate inputs with G and D , and fuzz them
- 3: $s = \text{ChooseNext}(s)$
- 4: deterministically fuzz with s if needed
- 5: mutate s in havoc/splicing style and fuzz the mutated inputs
- 6: mutate s in syntax-aware style with G and fuzz the mutated inputs
- 7: **until** *timeout* reached or user *aborts*

Output: Crash inputs s_c

Algorithm 2 Data construction for fuzzing.

Input: a set of data types T , number of data to create for each type N , maximum number of values inside each data N_f

- 1: $D = \phi$ ▷ The data to output
- 2: $V = \phi$
- 3: add predefined different values to V
- 4: **for** each data type t in T **do**
- 5: **for** i from 1 to N **do**
- 6: create data item d of type t
- 7: $n_f = \text{UniformRandom}(1, N_f)$
- 8: **for** j from 1 to $|V|$ **do**
- 9: add the corresponding value of V to d
- 10: **end for**
- 11: **for** j from $|V| + 1$ to n_f **do**
- 12: add a random string value to d
- 13: **end for**
- 14: add d to D
- 15: **end for**
- 16: **end for**

Output: data set D

136 In addition to the havoc/splicing stage, DAFuzz contains a syntax-aware mutation stage like Superior
 137 (Wang et al., 2019) for improving the ratio of valid inputs obtained from seed mutation.

138 3.2 Data Construction

139 The data construction module is to construct a data set containing different types of data, which is later
 140 provided to program execution and input generation. The algorithm is shown in Algorithm 2. Users could
 141 specify the set of data types T to generate (e.g., *list* and *hash*), the number of data items N to create
 142 for each type, and the maximum number of values N_f to store in each data item (e.g., the number of
 143 members in *list*). In the algorithm, a small set of predefined values V is prepared first. Then, for each
 144 data type, N data items would be generated. For generating each data item, its number of members n_f
 145 is randomly obtained by $\text{UniformRandom}(1, N_f)$ (uniformly selected in $[1, N_f]$). After that, both the
 146 predefined values V and some randomly generated strings are added to the data item, according to n_f .
 147 The predefined value set V is useful since it makes sure that the data items have common values, which
 148 makes the calculations (e.g., the intersection) among them may not empty.

149 To run the algorithm, users should know the supported data types of the data store (PUT), and they
 150 usually should add all supported data types into T to construct different types of data, unless users just
 151 want to focus on fuzzing part of data types like in directed fuzzing (Böhme et al., 2017). In addition,
 152 however, it is better to specify moderate values for N and N_f , which define how much data to generate,
 153 because loading too much data when starting the server would slow down the fuzzing execution speed.

154 3.3 Data-aware and Semantics-aware Input Generation

155 The data-aware and semantics-aware input generation module is used to generate inputs according to the
 156 grammar of inputs and the data constructed in Section 3.2, and its algorithm is shown in Algorithm 3. For
 157 in-memory data stores, the grammar of inputs is mainly the grammar of commands, which consists of the
 158 name, options, and parameters of each command. In addition to the grammar and data set, DAFuzz also

Algorithm 3 Data-aware and semantics-aware input generation.

Input: command grammar G , command list C , command-to-related-commands map R , data set D , a normal distribution $N(\mu, \sigma^2)$ deciding the number of commands in an input.

```

1:  $s = \phi$ 
2:  $n_c = N(\mu, \sigma^2)$ 
3:  $next\_cmd = \text{SelectRandomCommand}(C)$ 
4: for  $i$  from 1 to  $n_c$  do
5:   create command  $c$  of type  $next\_cmd$  according to  $G$ 
6:   for each field  $f$  of data type  $t$  in  $c$  do
7:     if  $t$  exists in  $D$  then
8:       select a random data item in  $D$  of type  $t$  and fill the field  $f$ 
9:     else
10:      generate random data item and fill the field  $f$ 
11:    end if
12:  end for
13:  append  $c$  to  $s$ 
14:  if  $R[next\_cmd]$  is not empty then
15:     $next\_cmd = \text{SelectRandomCommand}(R[next\_cmd])$ 
16:  else
17:     $next\_cmd = \text{SelectRandomCommand}(C)$ 
18:  end if
19: end for

```

▷ The seed to output

Output: seed s

159 prepares a command list C containing all commands and an optional command-to-related-commands map
 160 R . The map R is a map that maps each command to a command list containing all its related commands,
 161 e.g., the related commands of *SINTER* command (*set* intersection command) including all commands
 162 about *set* calculations. The normal distribution $N(\mu, \sigma^2)$ is to define how many commands to put inside a
 163 single input. DAFuzz does not use uniform distribution here for having a small probability to generate
 164 extraordinarily big inputs.

165 In the input generation algorithm, the number of commands n_c in the input is first calculated. After
 166 that, the first command type is randomly selected from the command list C . Then, DAFuzz creates a
 167 command c of the given command type, with options of the command randomly enabled. The creation
 168 method is introduced later with examples. DAFuzz fills all fields of the command c before appending it to
 169 the seed. When filling a field of a data type, DAFuzz first tries to randomly select a data item from all the
 170 data items with the same data type in data set D . If no such data items exist in the data set, it randomly
 171 generates a data item with the given type. When selecting the next command type, if the current command
 172 has related commands in the map R , it obtains all related commands with $R[next_cmd]$ and randomly
 173 selects the next command. Otherwise, it still randomly selects a command type from the whole command
 174 list as the next command. Now the algorithm does not try to ensure the “normal” order of generated
 175 commands, because it is hard to define the “normal” order (e.g., hard to know which list command,
 176 LPOP or LPUSH, is normally executed first), and randomly executing commands may help to expose
 177 vulnerabilities in data stores.

178 We use examples to illustrate the aforementioned command creation, mainly about how options are
 179 enabled. Suppose the LPOP *key* [*count*] command is selected for creation (where “[]” means inner content
 180 is optional). DAFuzz randomly selects one from the two possible commands to create, LPOP *key* and
 181 LPOP *key count*, which means there are two possible values for the component “[*count*]”: “*count*” or “”
 182 (i.e., blank). Considering another ZADD command is selected and it has the grammar ZADD *key* [*NX*
 183 | *XX*] [*GT* | *LT*] [*CH*] [*INCR*] *score member* [*score member*] (where “[]” means any one of the listed
 184 elements is allowed). We can see that there are three possible values for the component “[*NX* | *XX*]”:
 185 “*NX*”, “*XX*”, or “” (i.e., blank). Thus, for the ZADD command, DAFuzz randomly selects one from the
 186 $3 \times 3 \times 2 \times 2 \times 2 = 72$ possible commands to create. The creation method is implemented by processing
 187 “[]” and “[]” symbols in multiple rounds until all of them are parsed, which could easily deal with the case
 188 that options are nested (e.g., “[[. . .]. . .]”).

189 3.4 Syntax-aware Mutation

190 DAFuzz uses the tree-based mutation method proposed in Superior (Wang et al., 2019) to mutate seeds,
 191 which could keep the syntax of test inputs correct. The tree-based mutation method generally works as

192 follows. It parses two seeds *tar* and *pro* into two abstract syntax trees first and collects all the subtrees
193 into a set *S*. Then, it iterates all the subtrees of the AST of *tar* one by one, and for each subtree obtains
194 a batch of new inputs, by replacing the subtree with each subtree in *S* once and serializing the mutated
195 AST to an input. DAFuzz follows the same method to mutate seeds, however, it uses the grammar of
196 in-memory data stores instead (e.g., the grammar of commands and the RESP protocol for Redis).

197 DAFuzz also adopts the enhanced dictionary-based mutation method proposed in (Wang et al., 2019),
198 which could cleverly mutate seeds by considering token boundaries (e.g., not partially overwriting tokens).
199 We add the names of commands and the names of data items in the constructed data set into the fuzzing
200 dictionary to better support the method.

201 Note that DAFuzz still would mutate seeds to produce inputs that are not syntactically or semantically
202 valid, since it still has the havoc/splicing stage as we mentioned in Algorithm 1. This is helpful to cover
203 exception handling code during fuzzing, and we do observe a higher code coverage in our testing.

204 4 IMPLEMENTATION

205 *Preparing the Grammars.* The grammars mainly include the grammars of commands and serialization
206 protocols and are obtained from corresponding official websites. For example, Redis has more than 300
207 commands in 6.x, and we retrieve its command grammar (including command name, options, parameters)
208 from <https://redis.io/commands/> with a web crawler written in Python. In the document for
209 each command, there is also a column for “Related commands”, which is used to build the command-to-
210 related-commands map. Redis may use both RESP and inline commands as its serialization protocol,
211 and DAFuzz supports both of them in its syntax-aware mutation.

212 *Data Construction.* The data constructed for Redis are stored into a rdb file, which is loaded when
213 starting the Redis server with the `--dbfilename` option. However, Memcached does not have a
214 mechanism to load data into the data store when starting the server, and the constructed data are loaded
215 by using commands that are inserted in the front of the initial seeds. The more data are constructed for
216 fuzzing, the higher probability that different data conditions would be satisfied during fuzzing. However,
217 the more data are loaded when starting the server, the slower the fuzzing execution speed would become.
218 For Redis, the rdb file we use for fuzzing is about 3.8KB, and we have tested that it does not slow
219 down the fuzzing execution speed too much, and also supports good code coverage.

220 *The Fuzzer.* DAFuzz is implemented based on Superior (Wang et al., 2019), which is further based
221 on AFL (Zalewski, 2017). We implement the data-aware and semantics-aware input generation method
222 using C++. We also use ANTLR (ANother Tool for Language Recognition) 4 (v4.9.3) for recognizing the
223 ASTs of seeds and making syntax-aware seed mutation, though with new grammars. Superior disables
224 the havoc/splice stage by default during fuzzing, but we find such a stage is useful for in-memory data
225 stores and we re-enable it.

226 5 EVALUATION

227 In this section, we evaluate our DAFuzz prototype, aiming to answer the following research questions.

- 228 • Does DAFuzz improve the code coverage when fuzzing in-memory data stores?
- 229 • Can DAFuzz find more vulnerabilities or find vulnerabilities more quickly?

230 5.1 Experiment Setup

231 **Programs.** We use the two most popular in-memory data stores, Redis and Memcached, for exper-
232 iments. For performance comparison, we use Redis unstable (master) branch with the last commit
233 #5460c10 (2022/1/3), and Memcached 1.6.13.

234 **Baseline Fuzzers.** We select several state-of-the-art fuzzers for comparisons, including AFL (Zalewski,
235 2017), Superior (Wang et al., 2019), AFLNET (Pham et al., 2020), and AFL++ (Fioraldi et al., 2020).
236 The first one is the latest AFL (v2.52b) (Zalewski, 2017). Superior (Wang et al., 2019) is a fuzzer that
237 supports grammar-aware (mainly syntax-aware) mutation. We update it with the grammar of commands
238 and network protocols of the two data stores. AFLNET (Pham et al., 2020) is selected because it is
239 specially designed for fuzzing network protocols, and we update it with the network protocols of the
240 two data stores as well. AFL++ (Fioraldi et al., 2020) (v4.00c) is the successor of AFL and has many
241 improvements like better seed scheduling, more mutators, and faster instrumentation. For all the fuzzers
242 we use their default parameters. All fuzzers are explicitly configured to skip the deterministic stage (i.e.,

Table 1. Average numbers of edges discovered after 24 hours, with the ratios in brackets representing how many more edges DAFuzz discovers than them.

Program	AFL	AFLNET	AFL++	Superion	DAFuzz
Redis	12913 (+18%)	7555 (+102%)	13043 (+17%)	13398 (+14%)	15257
Memcached	1989 (+9%)	1396 (+55%)	2037 (+6%)	1973 (+10%)	2167
Total	14902 (+17%)	8951 (+95%)	15080 (+16%)	15371 (+13%)	17424

with “-d” option), except AFLNET and AFL++, which have disabled the stage by default (Pham et al., 2020; Fioraldi et al., 2020). However, since Superion needs deterministic fuzzing for grammar-aware trimming and enhanced dictionary-based mutation (Wang et al., 2019), we still do deterministic fuzzing for seeds with a probability, even the “-d” option is set. We enable the probability for AFL, Superion, and DAFuzz for a fair comparison, but do not enable it for AFLNET and AFL++, which have disabled the deterministic stage by default. We set the probability to be 0.05 since we find it makes a good balance on different stages.

Fuzzing Parameters. For a fair comparison, we provide all the fuzzers with the same dictionary, the same initial seeds, and the same constructed data set (i.e., constructed as described in Section 3.2). The dictionary contains the names of data store commands and the names of data items in the data set. The program parameter of Redis is like `./redis-server --dbfilename data.rdb --bind 127.0.0.1 --protected-mode no`, where `data.rdb` is the file contains the constructed data set, and the program parameter of Memcached is like `./memcached`, and the constructed data are stored in initial seeds. We use a faster de-socketing tool, `desockmulti` (Zeng et al., 2020), for fuzzing both programs, since they communicate with their clients through sockets but not files or `stdin`, except for AFLNET which directly communicates with the PUTs through ordinary sockets.

Platform. The experiments are conducted on a server with 2 Intel(R) Xeon(R) CPU E5-2640 v4 @ 2.40GHz processors, 64GB RAM memory, and with 64-bit Ubuntu 20.04 LTS as server operating system. Each case lasts for 24 hours on a single core and is repeated 5 times if not explicitly stated, for reducing the randomness of fuzzing (Klees et al., 2018).

5.2 The Comparison of Code Coverage

Edge Coverage. Edge coverage (i.e., branch coverage) is used here since it is one of the most widely used coverage metrics now (Lemieux and Sen, 2018; Fioraldi et al., 2020; Wang et al., 2021a; Metzman et al., 2021; Fioraldi et al., 2022), and the edge coverage growth of different fuzzers is shown in Figure 4 and Figure 5, for Redis and Memcached respectively. We can see that DAFuzz outperforms all other fuzzers in both programs. AFL, Superion, and AFL++ perform similarly and are in the second tier, while AFLNET performs considerably worse. This is mainly because the execution speed of AFLNET is slow (e.g., less than 20 execs/s vs. over 100 execs/s for other fuzzers), which is a known problem (Zeng et al., 2020; Schumilo et al., 2022) since it feeds inputs to PUT through ordinary INET sockets but not faster UNIX sockets (Zeng et al., 2020). Superion outperforms its base fuzzer AFL in Redis while performs similarly in Memcached, which suggests that syntax-aware mutation (Section 3.4) may be only useful in some cases. In addition, DAFuzz performs much better than its base fuzzer Superion in both programs, which suggests that data-aware and semantics-aware input generation module (Section 3.3) could further boost the capability of the fuzzer, since the input generation module is the only difference between them in the experiment.

The final numbers of edges discovered by different fuzzers in 24 hours are shown in Table 1 for quantitative comparison. DAFuzz discovers 17424 edges in total in the two programs, which are 17%, 95%, 16%, and 13% more than AFL, AFLNET, AFL++, and Superion, respectively. We further calculate the time DAFuzz needs to discover the same number of edges other fuzzers discover in 24 hours and list the time and improvements of DAFuzz over others in Table 2. The number of edges is collected every 5 minutes. We can see that DAFuzz needs at most 1 hour and 15 minutes to discover the same number of edges any other fuzzer discovers in 24 hours, which means DAFuzz is at least 19× faster in edge discovery.

Statistical Analysis. We also use the p value of Mann Whitney U-test to decide whether there is a statistically significant difference between two sets of results, as suggested in (Klees et al., 2018). The p

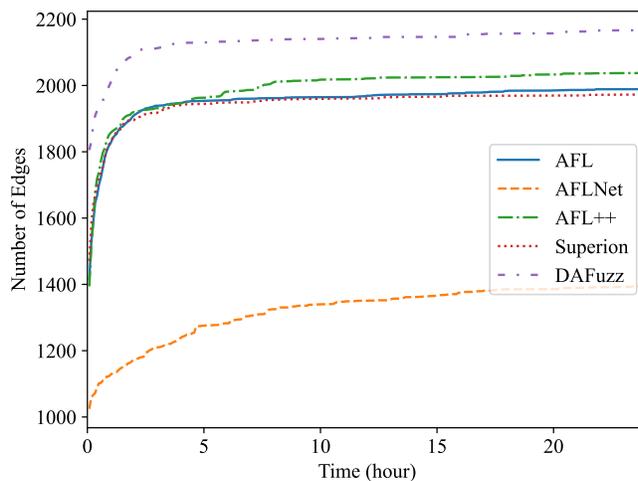

Figure 5. The edge coverage growth discovered by different fuzzers for Memcached

Table 2. The time needed by DAFuzz to discover the same numbers of edges discovered by other fuzzers in 24 hours (measured every 5 minutes), with the improvements DAFuzz over them placed in brackets.

Program	AFL	AFLNET	AFL++	Superion
Redis	40 mins (36×)	<5 mins (288×)	45 mins (32×)	1 hour 10 mins (21×)
Memcached	55 mins (26×)	<5 mins (288×)	1 hour 15 mins (19×)	50 mins (29×)

Table 3. The p values on the numbers of edges discovered by DAFuzz and other fuzzers.

Program	$p1$	$p2$	$p3$	$p4$
Redis	0.008	0.008	0.008	0.008
Memcached	0.008	0.008	0.008	0.008

Table 4. Average time needed for the vulnerability discovery, with the improvements of DAFuzz over them in brackets.

Unique Vulnerability	AFL	AFLNET	AFL++	Superion	DAFuzz
redis issue #10070 (segmentation violation)	12 mins	>24 hours	8 mins	16 mins	19 mins
redis issue #10076 (stack buffer overflow)	3 hours 43 mins	>24 hours	3 hours 29 mins	59 mins	9 mins
Total	3 hours 55 mins (8.4×)	>24 hours (>51.4×)	3 hours 37 mins (7.8×)	1 hour 15 mins (2.7×)	28 mins

288 values are shown in Table 3, where $p1$, $p2$, $p3$, $p4$, and $p5$ represent the differences between DAFuzz
 289 and the other four fuzzers, AFL, AFLNET, AFL++, and Superion respectively. p value is less than 0.05
 290 means the difference is statistically significant. Here all the p values are less than 0.01, which means the
 291 code coverage of DAFuzz is different from the code coverage of other fuzzers significantly.

292 5.3 The Comparison of Unique Vulnerability Discovery

293 All the fuzzers only discover crashes in Redis during performance comparison. We use AddressSanitizer
 294 (Serebryany et al., 2012) to rebuild the program, run it against the inputs that cause crashes, and manually
 295 remove duplicated vulnerabilities. Eventually, we confirm that two unique vulnerabilities (one segmenta-
 296 tion violation and one stack buffer overflow) are discovered by all fuzzers except AFLNET, which does
 297 not discover any vulnerabilities. We report the two vulnerabilities to developers in Github issue #10070 ⁵
 298 and issue #10076 ⁶ respectively. Both of them have been confirmed and fixed by the developers. We will
 299 describe their details later in Section 5.6, and focus on the comparison of vulnerability discovery speed
 300 here. Table 4 shows the average time needed for each fuzzer to discover the two vulnerabilities. DAFuzz
 301 only needs 28 minutes on average to find both of them, which is $2.7 \times$ faster than Superion (1 hour 15
 302 mins), $7.8 \times$ faster than AFL++ (3 hours 37 mins), and $8.4 \times$ faster than AFL (3 hours 55 mins).

303 5.4 The Effect of Using Constructed Data Only

304 In this subsection, we check the effect of the data construction module alone. In Section 5.2, since all
 305 fuzzers are provided with the constructed data as mentioned before, the comparison between Superion
 306 and AFL illustrates the effect of syntax-aware mutation module (Superion is based on AFL but with
 307 this extra mutation module), and the comparison between DAFuzz and Superion illustrate the effect of
 308 data-aware and semantics-aware input generation module (DAFuzz is based on Superion but with this
 309 extra generation module). It may be interesting to know the effect of using the data constructed alone,
 310 and we use the base fuzzer AFL as an example. Here, one AFL fuzzer uses the data constructed (marked
 311 as AFL), another AFL fuzzer has no data provided (marked as AFLNoData), and the result is shown in
 312 Figure 6 and Figure 7. The code coverage of AFL and AFLNoData is close in the figures. We confirm
 313 that by also using the p value of Mann Whitney U-test, and showing the p values in Table 5. Both p
 314 values are larger than 0.05, which means that there are no statistically significant differences between the
 315 two fuzzers. We think this may have several reasons. First, although code lines executed only when the
 316 constructed data are available are usually critical, they may be only a small portion of the whole code
 317 base. Second, code coverage may not reflect program state changes caused by satisfying different data
 318 conditions, since code coverage only cares about code paths newly being discovered but not variables
 319 getting new values (Aschermann et al., 2020; Fioraldi et al., 2021). Third, loading extra data when starting
 320 the PUT consumes more time. For example, the average executions per second of AFL and AFLNoData

⁵<https://github.com/redis/redis/issues/10070>

⁶<https://github.com/redis/redis/issues/10076>

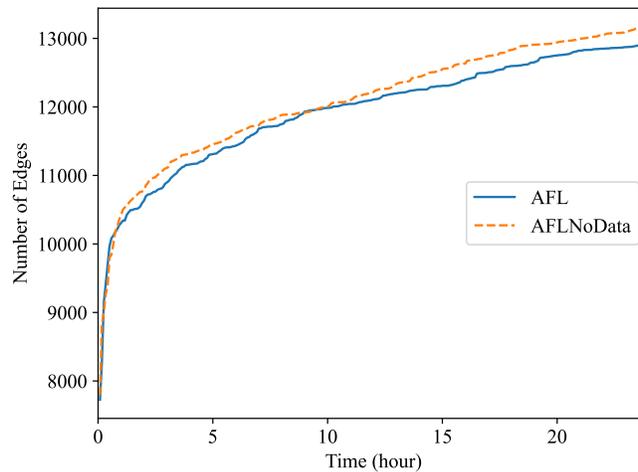

Figure 6. Fuzzing Redis with or without constructed data.

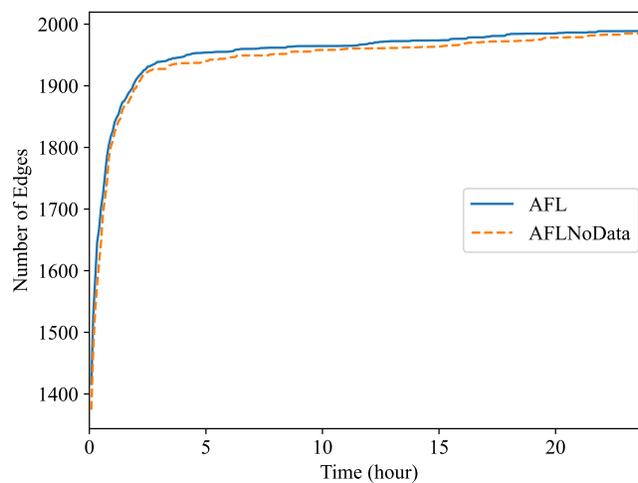

Figure 7. Fuzzing Memcached with or without constructed data.

321 are 134 exec/s and 137 exec/s for Redis, respectively. Thus, we can know that only using the constructed
 322 data may not improve the overall fuzzing efficiency, and other modules of DAFuzz are needed as well.

323

324 **5.5 The Effect of Multi-dimensional Fuzzing**

325 Recently multi-dimensional fuzzing (Xu et al., 2019; Schumilo et al., 2020; Zou et al., 2021; Xie
 326 et al., 2022) is proposed for fuzzing programs expecting two or more types of inputs at the same time. For
 327 example, two types of inputs, disk-image input and system-call input, are used for fuzzing file systems
 328 (Xu et al., 2019). In DAFuzz, the constructed data file provided for fuzzing may be considered as another
 329 type of input in addition to the command type input. Thus, we also test the effect of multi-dimensional
 330 fuzzing in DAFuzz, with a special mode we named DAFuzz-M. In DAFuzz-M mode, a seed contains two

Table 5. The p values on with or without constructed data.

Program	$p1$
Redis	0.310
Memcached	1.000

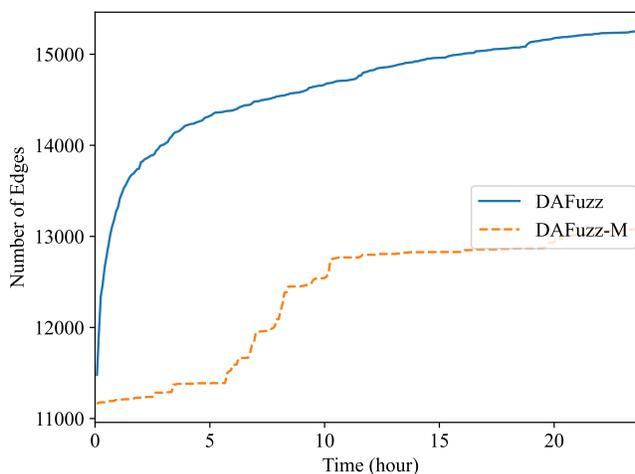

Figure 8. Fuzzing Redis using or not using multi-dimensional fuzzing.

Table 6. The vulnerabilities newly found by us.

Program	Version	Vulnerability Type	Github Issue No.	Status
Redis	unstable branch	segmentation violation	redis issue #10070	Fixed in 7.0
Redis	unstable branch	stack buffer overflow	redis issue #10076	Fixed in 7.0
Redis	6.2.1	segmentation violation	redis issue #8712	Fixed in 6.2.3
Memcached	1.6.9	segmentation violation	memcached issue #779	Fixed in 1.6.10

331 parts: the command input part and the data input part (although for simple implementation only the *index*
 332 of the data input part is actually stored in the seed, and the content of data input is stored in a queue similar
 333 to the original seed queue). During fuzzing, we follow the method in (Xu et al., 2019) by first mutating
 334 the data input part and using the original command input part of the seed to fuzz, and then mutating the
 335 command input part and using the original data input part to fuzz. We only test multi-dimensional fuzzing
 336 with Redis, since Memcached actually is fuzzed using one type of inputs (the constructed data for
 337 Memcached are also loaded by using commands inserted in the front of seeds as we explained before).
 338 The result is shown in Figure 8. However, DAFuzz-M has a lower code coverage than DAFuzz. We find it
 339 is mainly because the `rdb` file used as data input has a highly structured format⁷, and mutating such file
 340 could easily fail the checks during parsing (e.g., inserting a single byte may cause a later length field to
 341 read at a wrong position and get an invalidly large value). In addition, the command inputs of DAFuzz
 342 may also modify the data of the data store since the commands operate on the data as well, which makes
 343 the advantage of introducing the data inputs in another dimension not apparent.

344 5.6 Vulnerabilities Discovered

345 In the following, we briefly introduce the two vulnerabilities discovered during the performance com-
 346 parison experiments, and another two vulnerabilities we discovered previously with DAFuzz (we used
 347 DAFuzz to fuzz Redis 6.2.1 and Memcached 1.6.9 for finding bugs only and did not compare with
 348 other fuzzers). These vulnerabilities may be used for exploitation or DoS (Denial-of-Service) attack. They
 349 are shown in Table 6 and further explained below.

350 *Wrongly processing commands containing “|”* (redis issue #10070). Redis plans to treat sub-
 351 commands as commands in v7.0, which would allow having different ACL (access control list) cat-
 352 egories for subcommands. For example, “CONFIG GET” is allowed but not “CONFIG SET”, and
 353 users may send commands like “ACL SETUSER test +CONFIG|GET” to configure that. However,
 354 the processing codes added for splitting the command with “|” make some commands that contain “|”
 355 (e.g., “scard|setl”) wrongly pass the built-in “ERR unknown command” check, and crash in the func-
 356 tion `addReplySubcommandSyntaxError`. The developers fix the problem by introducing a new
 357 function `isContainerCommandBySds` in `server.c` to check whether a command is a container

⁷[https://github.com/sripathikrishnan/redis-rdb-tools/blob/master/docs/RDB_File_](https://github.com/sripathikrishnan/redis-rdb-tools/blob/master/docs/RDB_File_Format.textile)
 Format.textile

358 command (e.g., having subcommands) and reject the command early if it is not.

359 *Unexpected commands sent from replicas are not filtered* (redis issue #8712⁸, and #10076). Redis
360 supports high availability and failover with replication, and it only allows replicas to send limited
361 commands like REPLCONF and PING to the master. We find in Redis 6.2.1 that after a replica
362 sends a PSYNC and a FAILOVER command (meaning starting partial synchronization and coordinated
363 failover between the replica and the master), the replica sends other commands like SET would cause
364 segmentation violation in the master. Developers fix the issue by rejecting commands from replicas that
365 interact with the keyspace of the master in function `processCommand` of `server.c`. However, the fix
366 is incomplete unfortunately. In the unstable branch, we later find a stack buffer overflow that is triggered
367 by a PSYNC command with a following SLOWLOG command. The developers further add code in the
368 function `addReplyDeferredLen` of `networking.c` to disconnect replicas that send commands
369 on the replication link that cause replies to be generated.

370 *External storage is not checked for stats command* (memcached issue #779⁹). *Extstore* in Memcached
371 is to reduce memory footprint by leaving the hash table and keys in memory and moving values to external
372 storage (usually flash). However, in Memcached 1.6.9, a segmentation violation would be triggered when
373 “stats extstore” command is executed. This is because *extstore* is on by default but the server needs to be
374 started with `-o` option like `-o ext_path=/path/to/a/ datafile:5G`. Otherwise, an *extstore*
375 value is null but would be used if that “stats extstore” command is executed. Developers fix it simply by
376 adding a null check when processing the “stats” command in the function `process_extstore_stats`
377 of `storage.c`.

378 6 RELATED WORK

379 6.1 Coverage-guided Fuzzing

380 Starting with the invention of AFL in 2007 (Zalewski, 2017), coverage-guided fuzzing (CGF) is one of the
381 most popular fuzzing technologies (Manes et al., 2019; Li et al., 2021; Zhu et al., 2022). CGF fuzzers are
382 typical grey-box fuzzers, since they only collect lightweight coverage information of inputs, and use that
383 to guide the fuzzers to gradually explore the state space of the PUT (Zalewski, 2017; Hon, 2023; lib, 2023;
384 Fioraldi et al., 2020, 2022). In contrast, black-box fuzzers do not know any internal execution information
385 of the PUT (though they may know the grammar of inputs like Boofuzz (Boo, 2023)), and white-box
386 fuzzers know the most detailed information of the PUT (e.g., through symbolic execution) (Manes et al.,
387 2019). Moreover, CGF fuzzers usually are *mutation-based* since they mutate seeds to get new inputs,
388 but there are CGF fuzzers that are *generation-based* as well, which generate new inputs from scratch by
389 using the grammar (or say, model) information (Manes et al., 2019; Li et al., 2021; Zhu et al., 2022). For
390 example, syzkaller (Google, 2015) could mutate existing sequences of syscalls (i.e., seeds) and generate
391 new sequences of syscalls at the same time during fuzzing. DAFuzz follows the same approach. CGF
392 fuzzers have successfully been used to discover many vulnerabilities (Zalewski, 2017; Google Security
393 Team, 2018), and become popular in both the security industry (Zalewski, 2017; Hon, 2023; lib, 2023;
394 Fioraldi et al., 2020; Google Security Team, 2018) and academia (Böhme et al., 2016; Lemieux and Sen,
395 2018; Gan et al., 2018; Lyu et al., 2019; Pham et al., 2020; Aschermann et al., 2020; Yue et al., 2020;
396 Wang et al., 2021a; Lin et al., 2022; Fioraldi et al., 2022).

397 There are two kinds of fuzzing techniques that are related to the data-aware fuzzing technique proposed
398 here, but are actually different. One is fuzzing with the aid of data-flow information (Wang et al., 2010;
399 Rawat et al., 2017; Chen and Chen, 2018; Aschermann et al., 2019b; Gan et al., 2020; Mantovani et al.,
400 2022). CGF fuzzing usually uses control-flow information only, e.g., coverage based on the edges of
401 the control flow graph (CFG). However, by using techniques like dynamic taint analysis, fuzzers could
402 know information like which bytes of the inputs are used in branch instructions. Such information could
403 further guide the fuzzer to bypass magic-byte and checksum checks (Wang et al., 2010; Rawat et al.,
404 2017; Aschermann et al., 2019b), mutate seeds more efficiently (Chen and Chen, 2018; Gan et al., 2020;
405 Mantovani et al., 2022), or use as another interest feedback besides coverage feedback (Mantovani et al.,
406 2022). Generally, such data-flow information extra collected is about the data in the input, while in
407 DAFuzz the data concerned are stored in the in-memory data store (i.e., the PUT).

408 Another related technique is the recently proposed state-aware fuzzing (Aschermann et al., 2020;

⁸<https://github.com/redis/redis/issues/8712>

⁹<https://github.com/memcached/memcached/issues/779>

409 Fioraldi et al., 2021; Ba et al., 2022). It usually considers the whole program state space to be divided
410 into different regions by different values of some important variables. Such important variables could
411 be variables representing the states of protocols (Aschermann et al., 2020; Ba et al., 2022), or variables
412 that stay the same values for most inputs but change to other values for some inputs (Fioraldi et al.,
413 2021). The CGF fuzzers detect the important variables either manually (Aschermann et al., 2020) or
414 automatically (Fioraldi et al., 2021; Ba et al., 2022) and use them together to guide the exploration of state
415 space during fuzzing. Different from DAFuzz, state-aware fuzzing also usually concerns the important
416 variables related to the input but not the data stored in the program. In addition, the important variables
417 usually are variables related to the switching of execution paths, but DAFuzz directly concerns the data
418 and may work even if no such variables are explicitly defined.

419 6.2 Grammar-aware Fuzzing

420 There are black-box (Peach Tech, 2020; Boo, 2023), grey-box (Pham et al., 2021), and white-box
421 (Godefroid et al., 2008) fuzzers that support grammar-aware fuzzing. For example, black-box fuzzers like
422 Peach (Peach Tech, 2020) and Boofuzz (Boo, 2023) use XML configuration files or code to define the
423 format of inputs to generate inputs, and white-box fuzzers like (Godefroid et al., 2008) may generate extra
424 constraints using the grammar of inputs. For grey-box fuzzers, researchers have found that CGF fuzzers
425 do not perform well for programs expecting structural inputs, such as Javascript engines, XML parsers,
426 etc., because when mutating seeds to get new inputs, it is easy to get invalid inputs (Wang et al., 2019),
427 which cannot pass the syntax and semantics checks early in the program execution. Thus, grammar-aware
428 CGF is proposed recently.

429 Grammar-aware CGF could roughly be divided into syntax-aware (Pham et al., 2021; Wang et al.,
430 2019; Padhye et al., 2018; Aschermann et al., 2019a; Pham et al., 2020; Salls et al., 2021), and semantics-
431 aware fuzzing (Han et al., 2019; Park et al., 2020; He et al., 2021). Syntax-aware fuzzing tries to ensure
432 the inputs mutated from seeds are still in the correct format. For example, they may convert seeds
433 into abstract syntax trees (ASTs) and mutate at the tree node level (i.e., tree-based mutation) to ensure
434 the inputs serialized from mutated ASTs still have correct Javascript statements (Wang et al., 2019).
435 Semantics-aware fuzzing tries to further ensure the inputs mutated from seeds have valid semantics.
436 For example, they may inspect the Javascript code or runtime errors to ensure the variables are defined
437 before use (Han et al., 2019; Park et al., 2020; He et al., 2021). DAFuzz adopts the same tree-based
438 syntax-aware mutation (Wang et al., 2019), which is enough since in-memory data stores usually could
439 use data variables without defining them first. However, different from the existing work, DAFuzz also
440 generates data-aware and semantics-aware new inputs, which is to ensure that different data items are
441 correctly referred to in the inputs.

442 6.3 Data-related Program Fuzzing

443 There are researchers focusing on fuzzing data-related programs. For in-memory data store, Google
444 security researchers fuzzed `Redis` but only used existing ordinary fuzzers like AFL (Google Information
445 Security Engineering Team, 2020). Another kind of data-related program is SQL database, and different
446 special black-box fuzzers (Seltenreich et al., 2022; Guo, 2017; Rigger, 2023; Rigger and Su, 2020) and
447 grey-box fuzzers (Zhong et al., 2020; Wang et al., 2021b; Liang et al., 2022) have been developed. At first,
448 fuzzers mainly focus on keeping the generated or mutated SQL statements syntactically valid (Seltenreich
449 et al., 2022; Guo, 2017). Recently, fuzzers also try to ensure the statements are semantically valid (Rigger,
450 2023; Rigger and Su, 2020; Zhong et al., 2020; Wang et al., 2021b; Liang et al., 2022). For example, they
451 ensure that the used tables are created first and the mentioned columns still exist (Zhong et al., 2020; Liang
452 et al., 2022). Several recent pieces of research focus on detecting logic bugs but not traditional crashes or
453 assert failures (Rigger, 2023; Rigger and Su, 2020; Liang et al., 2022). However, all these previous works
454 do not intentionally create different kinds of data as DAFuzz does for providing the required data, and all
455 these fuzzers are tightly bound to the SQL language and cannot work with in-memory data stores that use
456 other languages.

457 7 CONCLUSION

458 To exercise the code paths of in-memory data stores that require different data, we presented a new fuzzing
459 approach DAFuzz. DAFuzz could not only generate inputs that are syntactically and semantically valid
460 but also use different data correctly. In addition, DAFuzz adopts the state-of-the-art tree-based mutation

461 method as well. The comparisons with other state-of-the-art fuzzers like AFL, AFL++, Superion, and
462 AFLNET in two popular in-memory data stores Redis and Memcached showed that DAFuzz could
463 discover 13%~95% more edges, or discover the same number of edges at least 19× faster. Furthermore,
464 DAFuzz found the same vulnerabilities but over 2.7× faster. We newly found 3 vulnerabilities in
465 Redis and 1 vulnerability in Memcached, and reported them to developers. All vulnerabilities have
466 been acknowledged and fixed. We also think the idea of data-aware fuzzing could be applied to other
467 in-memory data stores like Dragonfly as well.
