Alzheimer's disease (AD) is an irreversible neurodegenerative disease with a high prevalence in the elderly population over 65 years of age. The intervention in the early stages of AD is of great significance to alleviate the symptom. Recent advances in deep learning have shown extremely advantages in computer-aided diagnosis of AD. However, most studies only focus on extracting features from slices in specific direction or whole brain images, ignoring the complementarity between features from different angles. To overcome the above problem, attention-based multi-view slice fusion (AMSF) is proposed for accurate early diagnosis of AD. It adopts the fusion of three dimensional global features with multi-view 2D slices features by using an attention mechanism to guide the fusion of slice features for each view, in order to generate a comprehensive representation of the MRI images for classification. The experiments on public dataset demonstrate that AMSF achieves the significant improvements over several previous promising methods. It indicates that the better solution for AD early diagnosis not only depends on the large scale of dataset, but also the organically combination of feature construction strategy and deep neural networks.

## Abstract

Alzheimer's disease (AD) is an irreversible neurodegenerative disease with a high prevalence in the elderly population over 65 years of age. Intervention in the early stages of AD is of great significance to alleviate the symptom. Recent advances in deep learning have shown extreme advantages in computer-aided diagnosis of AD. However, most studies only focus on extracting features from slices in specific direction or whole brain images, ignoring the complementarity between features from different angles. To overcome the above problem, attention-based multi-view slice fusion (AMSF) is proposed for accurate early diagnosis of AD. It adopts the fusion of three-dimensional global features with multi-view 2D slice features by using an attention mechanism to guide the fusion of slice features for each view, to generate a comprehensive

representation of the MRI images for classification. The experiments on the public dataset demonstrate that AMSF achieves significant improvements over several previous promising methods. It indicates that the better solution for AD early diagnosis is not only depends on the large scale of dataset, but also the organic combination of feature construction strategy and deep neural networks.

## Introduction

AD is a neurodegenerative disease with a high prevalence in people over 65 years of age (Reiman et al. 2012). Previous studies have shown that the structural changes in the brain caused by AD can be traced back 20 years before the onset of symptoms in patients (Barthelemy et al. 2020). In the early stages of AD, patients may not notice any significant changes in their brain structure or activity, but some difficulties with memory recall or retention may appear. As AD progresses, it leads to the formation of brain tissue lesions that impair and ultimately destroy neurons responsible for various cognitive functions (Zarei et al. 2013), including deterioration of memory and thinking skills, as well as a decline in physical abilities and independence. Patients with AD may present symptoms such as memory loss, cognitive impairment, language difficulties, and reduced mobility (Gaugler et al. 2022).

The global community is currently confronted with a significant demographic predicament characterized by a rapid expansion in the population of older individuals. As per the United Nations, the proportion of individuals aged 65 years and above in the overall global population is projected to reach 9.7% by 2022, and further escalate to 16.4% by 2050 (ECONOMIC & AFFAIRS. 2023). This unprecedented surge in ageing demographics presents formidable challenges for healthcare systems, given the heightened vulnerability of older adults to chronic and degenerative ailments. Among these conditions, AD stands out as a highly prevalent and debilitating disorder that profoundly impacts the cognitive and functional capacities of countless individuals across the globe.

Mild cognitive impairment (MCI) represents a pivotal transitional phase between normal ageing and dementia, characterized by a discernible cognitive decline that does not significantly impede daily functioning. MCI assumes a critical role as an early intervention window, presenting a valuable opportunity to mitigate or forestall subsequent cognitive deterioration (Wee et al. 2012). Extensive research has established that individuals diagnosed with MCI face a heightened susceptibility to developing AD, with an annual conversion rate ranging from 10% to 15% (Roberts & Knopman 2013). Consequently, the implementation of timely and efficacious medical interventions during the MCI stage holds the potential to safeguard neural cells against further impairment and delay the onset of AD pathology, thereby contributing to a reduction in the mortality associated with this incurable affliction (Odusami et al. 2022).

Neuroimaging serves as a valuable and indispensable tool in the clinical diagnosis of AD, enabling the quantification of structural and functional alterations within the brain that accompany disease progression. Among the diverse array of neuroimaging modalities available, magnetic resonance imaging (MRI) has garnered considerable attention owing to its high spatial resolution and non-invasive characteristics. Through MRI, intricate details regarding brain volume, cortical thickness, white matter integrity, and cerebral blood flow in AD patients can be gleaned. Notably, the advent of deep learning techniques has emerged as a formidable approach

for medical image analysis across a wide range of conditions, encompassing neurodegenerative disorders, orthopaedic ailments, and cancer. Leveraging the intrinsic capacity to automatically learn and extract intricate features from image data through the construction of multilayer neural networks, deep learning methods transcend conventional machine learning approaches by iteratively optimizing models with large-scale data. This obviates the need for manual feature engineering, engenders enhanced diagnostic accuracy, and improves overall diagnostic efficiency.

The integration of deep learning techniques into AD diagnostic research has been instrumental in the development of algorithms aimed at supporting physicians in early diagnosis and prognosis prediction. By harnessing the power of deep learning for MRI analysis, the detection of AD at its nascent stages becomes attainable, thereby augmenting the diagnostic capabilities and precision of healthcare professionals. This, in turn, facilitates the timely implementation of intervention strategies to mitigate further cognitive decline. The exploration of deep learning-based early AD diagnosis holds significant theoretical and practical implications, encompassing the identification of initial brain alterations in AD patients, the enhancement of AD diagnostic efficiency, the amelioration of the quality of life for individuals afflicted by AD, and the advancement of deep learning theory as a whole.

Deep learning has become increasingly prominent in medical image analysis, surpassing conventional machine learning algorithms in various domains (Lian et al. 2020). Notably, its automated feature learning capability from raw data, without the need for human intervention or domain expertise, distinguishes it as a highly advantageous approach. Among the array of deep learning models, Convolutional Neural Networks (CNNs) have demonstrated remarkable success and widespread adoption for medical image analysis. This can be attributed to their proficiency in capturing both spatial and semantic information from images, thereby enabling robust and accurate analysis in the medical field.

Korolev et al. (Korolev et al. 2017) explored the use of 3D CNNs for AD classification and developed two 3D CNN models that achieved comparable results to traditional methods using ADNI data. Cheng et al. (Cheng et al. 2017) employed 3D CNNs for AD classification, but they amalgamated multiple 3D CNNs by training them on MRI data from distinct brain regions and subsequently appending an FC layer to each one. Improved AD diagnosis performance of 3D CNNs was achieved by Zhang et al. (Zhang et al. 2021) through the incorporation of an attention mechanism, which enabled the network to selectively focus on relevant features. Spasov et al. (Spasov et al. 2019) proposed a method to reduce the computational complexity of 3D CNNs by using separable convolution techniques.

Pan et al. (Pan et al. 2022) invented an adaptive interpretable ensemble model (3DCNN+EL+GA) that leverages the power of 3DCNN, ensemble learning and genetic algorithm (GA) for AD classification and biomarker discovery. 246 base classifiers (3DCNN) were trained on a dataset of 246 brain regions and a majority voting scheme was employed to select the optimal combination of base classifiers from the set of classifiers by using GA. Liu et al. (Liu et al. 2020) developed a multi-task deep CNN model that performed both hippocampal segmentation and disease classification tasks simultaneously. They combined a 3D densely connected convolutional network (3D DenseNet) with the hippocampal segmentation results to learn richer features for AD diagnosis.

Khvostikov et al. (Khvostikov et al. 2018) built 3D CNNs for AD classification by extracting hippocampal ROIs from sMRI and DTI data. They also balanced the classes of different sizes by using data augmentation methods and investigated the effect of ROI size on classification results.

Liu et al. (Liu et al. 2018) developed an end-to-end approach for AD classification by extracting local fMRI image patches centred on predefined anatomical landmarks. These patches are applied to capture both the local and global structural features from the images. However, many of these 3D deep learning-based approaches still excessively rely on pre-determined ROIs before the training of the network, which may limit the performance due to the presence of irrelevant features in sMRI for AD diagnosis. Moreover, most of these studies only focus on binary classification, which is not very helpful for determining the stage of the patient's situation.

Each individual's brain exhibits unique characteristics and may possess disease-related features that cannot be fully captured by a single MRI slice. Consequently, the MRI slices of patients may exhibit minimal deviation from those of healthy individuals, making classification challenging. Previous studies have primarily focused on extracting features from specific slices or the entire image, disregarding the features of slices from different views and the complementary nature of features across these slices. Moreover, they have not effectively utilized the comprehensive structural information available in whole-brain MRI scans (Lian et al. 2022). In light of this, Qiao et al. (Qiao et al. 2021) proposed a novel approach for early AD diagnosis based on MRI, which involves extracting fused global features from multi-view slice features. They employed a simple splicing technique to combine the features of multiple slices from the same view. However, it is restricted by an assumption that all slices are of equal importance for the classification task. Different slices may contribute differently to disease features. Therefore, using equal weights for feature fusion may not effectively capture the relevant features, potentially resulting in lower classification accuracy.

Actually, the slices from the same view capture diverse brain regions and exhibit distinct features, essentially representing channel-specific mappings that reflect varying degrees of importance in the slice clusters. Additionally, it is essential to recognize that slices from different locations are not isolated entities but interconnected, collectively forming a comprehensive feature representation of the slice cluster in that specific direction. Hence, when fusing the features of different slices from the same view, it becomes crucial to consider both the significance of the information carried by each slice and the contextual relationship that exists between them. By incorporating these factors into the fusion process, a more robust and informative representation can be achieved, facilitating improved accuracy in capturing essential features for classification tasks, such as early AD diagnosis based on MRI data.

In this dissertation, a novel approach to the early diagnosis of AD called ASMF is proposed. Firstly, the Multi-view Slice-level Feature Extraction (MSFE) method is employed to acquire slice-level features from three distinct views (sagittal, coronal, and cross-sectional) by repeatedly slicing the 3D MRI and leverage three separate 2D sub-networks to extract features from each view. Then, an attention mechanism is incorporated to guide the fusion of slice features for each view, assigning varying weights to individual slices based on their respective importance. Secondly, global features are extracted from the entire MRI images by using a 3D CNN to complement the slice-level features. Finally, the slice-level and global features are fused to generate a more comprehensive feature representation for the classifier. The key contributions of this study can be concluded as follows:

1. To address the limitations of relying on feature extraction in a specific direction, this study proposes a novel MSFE-based approach for early diagnosis of AD.
2. This is the first study that incorporates the self-attention mechanism and the fusion of multi-view features to construct a comprehensive representation of the MRI images for classification.

3. According to the experimental results, the proposed method outperforms other recently published promising approaches.

The remainder of this paper is arranged as follows. The materials and methods are described in Section 2. Section 3 provides experimental results and corresponding discussion. At last, the summary of this study is given in Section 4.

## Materials & Methods

In contrast to previous studies that typically rely on a single slice from a specific view for AD diagnosis, we utilize multiple slices from three views of 3D MRI scans to extract features. As shown in Fig. 1, by incorporating information from various slices, we aim to capture the full extent of brain damage caused by AD, accounting for patient heterogeneity. To guide the fusion of slice features, an attention mechanism is employed that assigns different weights to slices based on their relevance for classification. It ensures that the most informative slices contribute more significantly to the diagnostic process. Furthermore, we integrate the slice features from the three views with global features extracted from the entire MRI images, resulting in a feature representation that comprehensively reflects the overall brain state of the patient.

### Multi-view slicing feature extraction

To facilitate the analysis of the 3D MRI data, we initially partitioned it into three distinct planes: sagittal, coronal, and transverse planes. Each plane represents a different orientation of the brain and provides unique information about its structural characteristics. To ensure a comprehensive assessment, we extracted a total of 40 slices per view, thereby constructing a robust slice cluster. Figure 2 visually illustrates the resulting set of images, showcasing the diversity and coverage achieved across the different planes. By encompassing multiple slices from each view, our approach captures a broader range of relevant features, enabling a more thorough examination of the brain's structural attributes.

To extract features from each slice of the 3D MRI data, we used a slice-level feature extraction network that takes slice clusters as input. A slice cluster consists of 40 slices from one of three possible views: sagittal (x), coronal (y) or transverse (z), which represent different orientations of the brain structure and contain different types of features. Therefore, we designed a separate Slice Feature Extraction Network (SFEN) for each view. For instance, the sagittal view (x),  $C_x$  denotes the cluster of slices in this direction. Each slice in this cluster has an index  $i$  that ranges from 1 to 40. Thus,  $C_x$  can be written as

$$C_x = [C_x^1, C_x^2, \dots, C_x^n] \quad (1)$$

where  $n$  denotes the number of slices in the x-direction. The feature extraction of the  $i$ -th slice in the x-direction can be expressed as

$$T_x^i = \text{AvgPool}(F_x(C_x^i W_x^i)) \quad (2)$$

where  $F_x$  represents the feature extraction function consisting of multiple blocks containing a 3\*3 convolutional layer, BN layer, activation function ReLU and maximum pooling layer, as shown in Fig. 3. Besides,  $W_x^i$  denotes the convolutional layer weight of the  $i$ -th slice in the x-direction,  $T_x$  stands for the features of the cluster of slices in the x-direction after  $F_x$ . Then the slice cluster feature in the x-direction can be expressed as

$$T_x = [T_x^1, T_x^2, \dots, T_x^n] \quad (3)$$

## Attention-based slice feature fusion

To integrate the distinct features within each view (x, y, or z), we leverage the notion of a "slice cluster" comprising 40 slices that possess unique characteristics. These features serve as mappings for specific brain structures observed from their respective perspectives. Notably, these features are not isolated entities, but rather interconnected across various locations within the slice cluster. Consequently, they collectively establish a comprehensive feature representation for the given view. To effectively merge these features, it is imperative to consider both their significance and their interdependencies. To address this, we propose a novel mechanism termed Slices Fusion Attention (SFA). SFA employs self-attention to capture contextual information among the slices and assigns attention weights to each slice based on its relative importance and contribution to the overall feature representation of the view. By incorporating this attention-based weighting scheme, SFA effectively balances the significance of different slices while enriching them with contextual information derived from their interrelationships. Figure 4 provides an illustrative depiction of the structural composition of SFA.

We feed the slice cluster feature  $T_x$  into SFA as input.  $T_x$  has a dimension of  $40 \times 1 \times 128$  and it is obtained by concatenating the features of 40 slices along the channel dimension after applying SFEN. To reduce the number of channels from 128 to 1, we use a  $1 \times 1$  convolution layer that compresses  $T_x$  into a single-channel feature map. This gives us an aggregated feature that represents the fusion of 40 slices. Next, we apply a Softmax function to  $T_x$  and multiply it with  $S_x$ . This way, we obtain  $S_x$  that contains contextual information between slices weighted by their attention scores. We can write this process as

$$S_x = T_x^* * \text{Softmax}(\text{Conv}(T_x)) \quad (4)$$

where Conv means  $1 \times 1$  convolution operation, and  $T_x^*$  is obtained by reducing one dimension of  $T_x$ .

$S_x$  contains the contextual relationship between different slices, which needs to be assigned to each slice by calculating the slice feature weights of different channels. Firstly,  $S_x$  is expanded by one dimension and the number of channels is reduced by  $1 \times 1$  convolution, then BatchNorm and ReLU activation function operations are performed, and the number of channels is raised to the original number by  $1 \times 1$  convolution, denoted as

$$A_x = \text{Conv}(\text{BR}(\text{Conv}(S_x'))) \quad (5)$$

where  $S_x'$  is obtained by adding one dimension to  $S_x$ , and BR denotes the BatchNorm and ReLU activation functions.

$A_x$  is applied to represent the reweighted channel features that reflect how much each slice contributes to  $S_x$ . To obtain the slice fusion feature that incorporates both channel weights and contextual relationships between slices, we multiply  $A_x$  with  $T_x$  along the channel axis and sum them up. We denote this final output as

$$F_x = \sum_{i=1}^{40} T_x^i * A_x^i \quad (6)$$

where 40 denotes the number of slices and  $A_x^i$  denotes the  $i$ -th channel of weight  $A_x$ .

### Global feature extraction

The global feature extraction (GFE) component contains four blocks, each encompassing a sequence of operations: a 3D convolutional layer, a 3D batch normalization layer (BN), a rectified linear unit (ReLU) activation function, and a 3D maximum pooling layer. Subsequently, a 3D average pooling layer is employed to convert the multichannel features into a vector that encapsulates the global information. Figure 5 provides the structure of GFE. Following the acquisition of the global features, adaptive average pooling is applied to generate a one-dimensional vector. The multi-view slice-level features are then concatenated with the global vector. Finally, a fully connected layer is employed to obtain the ultimate classification outcomes.

274 Neuroimageing Initiative (ADNI) dataset (<http://adni.loni.usc.edu/>) is employed in this study.  
 275 ADNI provides data processed by standard volumetric analysis methods, including gradient non-  
 276 linearity correction, B1 correction, N3 correction, CAT12 for extraneous tissue removal,

alignment and smoothing operations. Then, a total of 351 3D-MRI scans for NC subjects are acquired (301 3D-MRI scans for AD subjects and 331 3D-MRI scans for MCI subjects).

In the experiments, the ADNI data were utilized and underwent several preprocessing steps before being fed into the feature extraction network, as depicted in Fig. 4. Initially, the background information that is unrelated to the classification task was eliminated. Subsequently, the image size was adjusted to  $90 \times 90 \times 90$ , and the image density was normalized based on the mean and standard values of the non-zero region. The 3D MRI data were then sliced according to three directions, and for each view, the middle 40 slices were selected. Finally, feature extraction operations were conducted on the obtained slices.

## Results and Discussion

### Ablation experiments

To investigate the performance of the proposed framework, the indicators of Acc (Accuracy), Sen (Sensitivity), Spe (Specificity), Pre (Precision) and F1 (F1-score) are employed for evaluation. The ablation experiments are conducted with the detailed definition as follows :

1. 3D: 3D features are only obtained by 3D GFE.
2. 2D: only employ 2D features learned by MSFE.
3. 2D+3D: 2D and 3D features are extracted by MSFE and GFE.
4. SE+2D+3D: the combination of 2D+3D with SE.
5. AMSF (SFA+2D+3D): SFA-guided 2D+3D.

The results of the ablation experiments are shown in Table 1. It can be seen that the classification accuracy of 3D is the lowest (76.9%). The 2D method provides better performance with the classification accuracy improvement to 89.4%, which is 12.5% higher than 3D. With the help of fused global features, 2D+3D achieves 91.6% Acc better than only using 2D or 3D strategy. However, the inclusion of SE results in a decrease in classification accuracy by 1.8%, suggesting that SE fails to effectively address the imbalanced importance among different slices within the same view for this particular task. At last, it is demonstrated that AMSF reaches the highest accuracy of 94.3%, surpassing that of the 2D+ 3D and SE+2D+3D by 2.7% and 4.5% respectively. It also exceeds in F1 scores, Sen, Spe and Pre. This indicates that SFA effectively integrates contextual relationships between different slices, enabling it to balance their importance within a given view.

The curve of validation loss for each epoch is shown in Fig. 6. It can be seen that during the training process, the training loss decreases continuously in the first 20 epochs and keeps stable. The validation loss declines in the first 10 epochs, then falls in fluctuation before 25 epochs, and finally stabilises after 35 epochs. Figure 7 gives the curve of the accuracy for each epoch. With a zigzag rise before 35 epochs, the validation accuracy reaches saturation. As can be seen in Fig. 8, the classification of AD achieves the highest accuracy (97.0%), indicating that AMSF is more sensitive to the features of AD. The classification accuracy for NC is 95.4% with 4.6% misclassifying NC to MCI. For MCI, it obtains the worst performance (90.4%), as well as an 8.2% misclassifying MCI to AD. It can be observed that the subtle difference in features between MCI and AD are formidable to extract, which is still a significant problem in AD diagnosis.

### Comparison with other methods

An experimental comparison with previous promising approaches is also arranged, including two traditional machine learning-based approaches (JMMP-LRR, Liner SVM) and three deep learning-based methods (DemNet, Automatic CL and AdaBoost). The abstracts of these works are listed as follows:

1. Automatic CL (Gracias & Silveira 2022): curriculum learning is employed in the early diagnosis of AD based on a 3D CNN network, by incorporating task complexity, cognitive test scores, and ROI features, thereby enhancing the accurate classification of MCI.
2. Liner SVM (Yuan et al. 2022): Mr cortical and ApoE4 gene features are explored for AD classification and the optimal performance is achieved by an SVM classifier with higher sensitivity and specificity.
3. JMMP-LRR (Sheng et al. 2020): it aims to better alleviate the problem of small-sample, ultra-high-dimensional features, accompany by stable AD classification accuracy.
4. DemNet (Billones et al. 2016): an improved 16-layer VGGNet architecture is proposed with SOTA (state-of-the-art) classification results of AD vs. MCI vs. NC.
5. AdaBoost (Buyrukoğlu 2021): an ensemble learning method is designed for AD diagnosis with SOTA performance compared with different ensemble learning methods.

Table 2 shows the classification results on the ADNI dataset compared with other previous promising methods. It can be seen that ASMF achieves the best performance with 94.3% classification accuracy, which is 1.6% -7.1% higher than other related works. Surprisingly, only by using a small scale of dataset, traditional machine learning-based methods (Linner SVM and AdaBoost) surpass the other three deep learning-based approaches. Especially for Linner SVM, it outperforms Automatic CL and DemNet without the help of DNNs. Together these results provide important insights into the better solution for AD early diagnosis not only depends on the large scale of dataset, but also the organic combination of feature construction strategy and deep neural networks.

## Conclusions

This study proposes a novel AD diagnosis approach called AMSF to address the limitation of relying on the feature extraction in a specific direction. It incorporates multiple slices with feature extraction from different views of 3D MRI images and the fusion of slice cluster features from each view achieved through an attention mechanism. Furthermore, the GFE by the 3D network fusion is combined to obtain a comprehensive MRI feature representation. Based on the AD vs. MCI vs. NC classification tasks on the public ADNI dataset, the experimental results demonstrate significant advantages over several SOTA methods. Although the promising experimental results achieves, the drawback still exists to be addressed. For example, a dataset with a limited size may restrict the generalization of the proposed model for practical applications. In future, diverse datasets with large scales are required to enhance the robustness and reliability of the method.
