Simultaneous Escape Routing (SER) is escaping of circuit pins simultaneously from inside two or more pin arrays. This is comparatively difficult as compared to routing in a single array and has not been addressed by previous studies. The increase in pin array complexity has made the manual SER in PCBs a very inefficient and tedious task and there surely is need for the automated routing algorithms. In this work we propose network flow based optimal algorithm that uses integer linear program to solve SER problem and area routing problem in two stages. In the first stage, pins are escaped to the boundaries of pin arrays simultaneously. These escaped pins are connected with each other in the second stage. The proposed algorithm is tested for different benchmark sizes of grids and the results show that it is not only better in terms of routability but also outperforms existing state of the art algorithms in terms of time consumption. The existing algorithms either fails to achieve higher routability or have larger time complexities. Whereas the proposed algorithm achieves 99.9% routability and it is also independent of grid topology and component pin arrangement which shows the superiority of proposed algorithm over the existing algorithms.

## ABSTRACT

Simultaneous Escape Routing (SER) is escaping of circuit pins simultaneously from inside two or more pin arrays. This is comparatively difficult as compared to routing in a single array and has not been addressed by previous studies. The increase in pin array complexity has made the manual SER in PCBs a very inefficient and tedious task and there surely is need for the automated routing algorithms. In this work we propose network flow based optimal algorithm that uses integer linear program to solve simultaneous escape routing problem and area routing problem in two stages. In the first stage, pins are escaped to the boundaries of pin arrays simultaneously. These escaped pins are connected with each other in the second stage. We tested the proposed algorithm for different benchmark sizes of grids and the results show that it is not only better in terms of routability but also outperforms existing state of the art algorithms in terms of time consumption. The existing algorithms either fails to achieve higher routability or have larger time complexities. Whereas the proposed algorithm achieves 99.9% routability and it is also independent of grid topology and component pin arrangement which shows the superiority of proposed algorithm over the existing state of art algorithms.

## INTRODUCTION

Printed circuit boards (PCB) support and connect the electrical components and provide conduction between them. Design of PCB is one of the most important things in electrical circuit and plays a vital role in performance of the circuit. There are multiple Integrated circuits (ICs) which are placed on the PCB and ever evolving manufacturing techniques have increased the complexity of these ICs and PCBs. The enhanced manufacturing techniques have not only reduced the size of the package but, have also exponentially increased the number of pins in an IC. The footprints of ICs have shrunk in size while the number of pins have increased. Around 2000 pins are present in the modern day high end packages Yan et al. (2012) with very small routing resources. This makes the footprint of an IC a very dense entity and manual routing becomes a hectic task in such a dense environment. Some other constraints, in addition to the PCB density, such as planar and pairwise routing, and length matching Lee W Ritchey (2006); Mitzner (2009) are also inflicted upon PCB routing.

These constraints combined together with the increasing density of the packages impose a bigger challenge on the PCB routing and therefore, take manual routing out of the consideration. This is where the automated routers come into the play for the solution of these issues and are currently used for the PCB routing. Automated routers help solve various PCB routing problems including escape routing and the area routing problem. The escaping of pins to the array boundary is known as escape routing and connecting these escaped pins in the intermediate area is known as area routing. Escape routing and area routing together play very important role in PCB routing. The pins on boundary of a pin array can easily be escaped and connected to their corresponding pins by keeping the via constraint in mind. But there are many pins which are inside the pin array and they cannot be connected directly and have to be escaped towards the boundary first which is known as escape routing problem. Escape routing problem is

46 one of the critical challenges in the PCB design because the modern ICs have a pin array that contains  
47 a large number of pins. The studies show that escape routing has three different types Yan and Wong  
48 (2010); Yan et al. (2012) namely Unordered Escape, Ordered Escape and Simultaneous Escape Routing  
49 (*SER*). Ordered and unordered escape routing consider a single pin array while two ICs are considered  
50 simultaneously in *SER*.

51 Simultaneous escape routing (*SER*) is relatively less explored as compared to the ordered and  
52 unordered escape routing. *SER* is also considerably difficult to achieve because of the reason that instead  
53 of a single IC, there are two ICs in *SER* and their pins need to be escaped simultaneously so that they  
54 could be connected to each other. There are very few studies on *SER*, however Ozdal et al. (2007) can  
55 be considered as the pioneer as this work consider two pin arrays simultaneously for the first time and  
56 minimize the net ordering mismatch. This work generated different patterns for a single pin and then  
57 selects one of the patterns such that the mismatching in net ordering along the boundaries is minimized.  
58 They used polynomial time algorithm for smaller problems and use randomized algorithm approach for  
59 routing in the case of larger problems without the inclusion of performance constraints Ozdal et al. (2007).  
60 Some heuristic solutions Lee et al. (2013); Chin and Chen (2013) have also been proposed for *SER*  
61 problem via using boundary and planar routing. Either too much time is consumed by these solutions  
62 or the achieved routability is less than acceptable percentage. In our recent study Ali et al. (2017), we  
63 propose the solution to routability problem through a network flow approach where we introduce two  
64 different models; one is based on the links and second on nodes. They are introduced to solve *SER*  
65 problem in PCBs through optimization technique. The models are successful in routing over small grids  
66 but consumed too much time when run over the larger grids.

67 In this work, we extend our previous study Ali et al. (2017) in order to solve both the problems  
68 including *SER* and area routing while considering time and routability constraints for smaller as well as  
69 larger grids. In our previous work, we did not consider larger grids. This research propose an optimal  
70 routing algorithms for both *SER* and area routing for smaller and larger grids. The proposed algorithm  
71 uses the network flow approach to develop an integer linear program for solution of these two problems.  
72 The problems of simultaneous escape and area routing are solved in multiple stages. Two different integer  
73 linear programs are developed for these two stages. The first program simultaneously escapes the pin  
74 from inside of both the pin arrays in order to reach the boundary of pin arrays. The second program  
75 fetches the results from first program and the purpose of second program is to connect the escaped points  
76 with each other.

77 Existing *SER* solutions suffers from various challenges including fixed pattern generation and higher  
78 time complexity. Some solutions in literature also lead to the pin blockage problem and resource wastage.  
79 These studies employed randomized approaches and heuristic algorithms but fail to provide efficient  
80 solution. In this study, we provide an optimal solution having a time complexity of under a minute along  
81 with 99.9% routability for the problem of *SER* in the printed circuit boards. This shows that the proposed  
82 solution is better than the solutions existing in the literature in terms of routability, time complexity and  
83 computational costs. Followings are the contributions of this work:

- 84 • Mapping of the PCB routing problem to network flow routing problem,
- 85 • Proposal of an algorithm for solution of *SER* that uses an integer linear program and provides  
86 optimal solution,
- 87 • Proposal of an algorithm for area routing that uses an integer linear program and provides optimal  
88 solution,
- 89 • Linkage between the proposed algorithms to obtain the end-to-end routing,
- 90 • 99.9% routability for pins,
- 91 • Reduction of time complexity.

92 Rest of the paper is organized as: Related literature is described in the next section followed by  
93 problem formulation. Then proposed network flow approach and dual node based routing are detailed.  
94 We finally discuss results before concluding the work.

## 95 RELATED WORK

96 PCBs are widely used for the modern age electric circuits fabrication. The design of a PCB plays a vital  
97 role in the performance of electric circuits. The ever evolving technology has not only reduced the size of

98 ICs that are to be placed on the PCBs but has also increased the pin count of ICs. This makes the process  
99 of manual PCB routing a very hectic task and demands automated PCB routing. The problems that are to  
100 be solved in the PCB routing are escape routing, area routing, length matching, and number of layers that  
101 are to be used. Many studies in the literature have addressed these routing problems related to the PCBs.

102 Some studies have proposed the heuristics algorithms to obtain a length matching routing Zhang  
103 et al. (2015b) and others have used differential pair escape Li et al. (2012, 2019), single signal escape  
104 routing Wu and Wong (2013) or both Wang et al. (2014) for escape routing along with addressing the  
105 length matching problem. The most notable technique used for the PCB routing is optimization. There  
106 are various studies in literature that have mapped different PCB routing problems to the optimization  
107 problem such as longest common interval sequence problem Kong et al. (2007), multi-layer assignment  
108 problem Yan et al. (2009), network flow problem Sattar and Ignjatovic (2016), pin assignment and escape  
109 routing problem Lei and Mak (2015), and maximum disjoint set of boundary rectangles problem for bus  
110 routing Ahmadinejad and Zarrabi-Zadeh (2016). A recent study has proposed a routing method that is  
111 based upon maze and it uses a hierarchical scheme for bus routing and the proposed method uses a rip-up  
112 and re-route technique as well in order to improve the efficiency Chen et al. (2019).

113 There are different problems to be solved in the PCB routing as discussed earlier and one of the  
114 most important problem among these is the escape routing where the pins from inside of an IC are to  
115 be escaped to the boundary of IC. Many studies in the literature have proposed solutions for escape  
116 routing problem among which some have considered single layer Lei and Mak (2015) in the PCB while,  
117 multiple layers Bayless et al. (2016); Zhang et al. (2015a) have also been considered. There are studies  
118 that only consider escape routing McDaniel et al. (2014) while, there are some studies which consider  
119 other problems like length matching Zhang et al. (2015b); Yan (2015); Chang et al. (2019) along with the  
120 escape routing as well. Some have used staggered pin array Ho et al. (2013a,b) while others have used  
121 grid pin array Jiao and Dong (2016) as well. Apart from electrical circuits, escape routing is also used for  
122 designing micro-fluid biochips PCBs McDaniel et al. (2016). The most widely used technique for the  
123 solution of escape routing is the optimization theory and it has been used for the past many years and  
124 also been employed by the current studies Katagiri et al. (2016); Serrano et al. (2016); Ahmadinejad and  
125 Zarrabi-Zadeh (2016).

126 The problem of escape routing is not the only problem to which the optimization theory provides  
127 solution to. The optimization theory has also been deployed by several other fields in which routing of  
128 packets in the wireless networks is the most prominent one. There is a recent study in which optimization  
129 theory is used in the wireless sensor networks (WSNs) for the smart power grids Kurt et al. (2017).  
130 The authors have proposed a novel mixed integer program with the objective function of maximizing  
131 the lifetime of a WSN through joint optimization of data packet size and the transmission power level.  
132 Apart from wireless sensor networks, the rechargeable sensor networks also face the problem of energy  
133 harvesting. Optimization techniques have also been used in these types of networks in order to jointly  
134 optimize the data sensing and transmission and achieve a balanced energy allocation scheme Zhang  
135 et al. (2015c). The optimization theory is also used in addressing the power optimization issues of the  
136 communication systems to fulfill the different demands of different message types regarding the QoS,  
137 length of packet and transmission rates ?. The optimization theory has also been used to increase the  
138 efficiency of the urban rail timetable Xue et al. (2019). The authors propose a nonlinear integer program  
139 in order to obtain a rail timetable which is efficient. The model is then simplified into an integer program  
140 with a single objective. A 9.5% reduction in wasted capacity is achieved through the use of a genetic  
141 algorithm in this study.

142 The application of optimization theory is not only limited to the fields of communication and network-  
143 ing but it is also been used in the vehicle routing problem Thongkham and Kaewman (2019), network  
144 reconfiguration for Distribution Systems Guo et al. (2020), microgrid systems Wu et al. (2019), distributed  
145 energy resource allocation in virtual power plants Ko and Joo (2020), control of humanoid robots Tedrake  
146 (2017), smart grid ecosystem Koutsopoulos et al. (2016) and Computation of the Centroidal Voronoi  
147 Tessellations (CVT) that is widely used in the computer graphics Liu et al. (2016). Ozdal et al. Ozdal  
148 and Wong (2004, 2006) can be regarded as the initial work on SER as they consider two pin arrays  
149 simultaneously and minimize the net ordering mismatch. There are some studies in the literature that have  
150 proposed a simultaneous pin assignment Xiang et al. (2001); Wang et al. (1991), Ozdal et al. Ozdal and  
151 Wong (2004, 2006) propose a methodology to escape the pins to boundaries in such a way that crossings  
152 are minimized in the intermediate area. Polynomial time algorithm is used for smaller problems and

153 randomized algorithm approach is proposed for routing in the case of larger examples.

154 It is stated that the routing resources available inside the pin array are less as compared to the routing  
155 resources that are available in the intermediate area. This is because of the reason that pins are densely  
156 packed inside the pin array. Also, using vias is not allowed within the pin array and the routing inside  
157 pin array must be free from conflicts and overlapping. Via usage is allowed in the intermediate area as  
158 opposed to the pin arrays. The problem is formulated as to find out best escape routing solution within  
159 the pin array so that the conflicts in intermediate area are minimized. There are two phases to solve the  
160 problem. In the first phase, a single layer is taken at a time and maximum possible non conflicting routes  
161 are packed on that layer. The conflicted routes are routed on the next layer and hence, escape routing is  
162 completed in this manner Ozdal and Wong (2004, 2006).

163 In the second phase of problem solution, a congestion based net-by-net approach is used for routing in  
164 the intermediate area. Routing conflicts are allowed at the beginning and optimal solution is found by  
165 rip-up and re-route approach. The ripping up of routes that are formed in the first phase is discouraged  
166 and in order to find a conflict free route for all pins which is obtained eventually. A number of routing  
167 patterns are defined for each net and a polynomial time algorithm is proposed in order to choose the best  
168 possible combination from all the given possible routing patterns. The results for different industrial data  
169 sets are obtained which show that optimal routes are increased and time required for routing is decreased  
170 as compared to other algorithms. Although it is a good approach, but 99.9% routability is not achieved  
171 in the escape routing problem and too much time is taken in the area routing problem Ozdal and Wong  
172 (2004, 2006).

173 Same authors propose an algorithm in Ozdal et al. (2007) to solve the escape routing problems in  
174 multiple components simultaneously. Some design constraints have also been considered along with  
175 routing. The escape patterns considered in this algorithm are more generalized in comparison to the  
176 algorithm proposed in their previous research Ozdal and Wong (2004). The objective is to minimize the  
177 crossover in intermediate area, hence less via usage. For smaller circuits, results given by their proposed  
178 randomized algorithm are within 3% of optimal solution, but optimal solution is not achieved in the case  
179 of larger circuits due to time complexity. They have also assumed fixed pattern generation which can  
180 be successful in the case of smaller circuits where components are well aligned, but complex problems  
181 cannot be solved easily by using these approaches Ozdal and Wong (2004); Ozdal et al. (2007). B-Escape  
182 Luo et al. (2010); Luo et al. (2011) solves this issue by removing the consumed routing area by a pin and  
183 shrinking the boundary. B-Escape reduced the time complexity and also increased the routability but, it  
184 can cause pin blockage when certain area is removed and boundaries are shrunk. Also, the time taken to  
185 solve most of the problems is still greater than one minute which is not optimal and needs to be reduced  
186 further than that Luo et al. (2010); Luo et al. (2011).

187 In addition to the above mentioned studies, other techniques have also been used in the literature for  
188 SER solution and one of them is negotiated congestion based routing scheme Qiang Ma et al. (2010)  
189 . Negotiated congestion based routing already has its application in FPGA routing. However, it is not  
190 being used for solving SER problem. A negotiated congestion based router is proposed which applies the  
191 negotiated congestion routing scheme on an underlying routing graph. In negotiated congestion approach,  
192 all pins are forced to negotiate for a resource which is the routing space in case of PCB. The pin needing  
193 most resources is determined. Some resources are shared between pins and these pins are routed again and  
194 again iteratively till no resources are shared among the pins. Results have been compared with Cadence  
195 PCB router Allegro and it was found that proposed router is able to achieve 99.9% routability in case  
196 of such circuits which are not routed completely by the Allegro. Time consumption is also less, but the  
197 issue is that there are some examples in which the proposed router is not able to achieve 99.9% routability  
198 while Allegro is able to achieve. It is proposed that the router should be used in collaboration with Allegro  
199 so that all the problems can be solved.

200 There is another research Yan et al. (2011) which uses ordered escape routing in order to solve the  
201 SER problem. The SER problem is solved by determining the net order. A bipartite graph is created on  
202 the basis of location of escape pins and transformation of net numbers is done. After doing SER, the net  
203 numbers are recovered. Basically, the orders of escape nets are found along the boundary in such a way  
204 that there is no crossover in the intermediate area. This approach achieves 99.9% routability along with  
205 reduction in time consumption, but the achieved net order is not routable in all cases. This approach can  
206 fail in some specific cases where the ordering proposed by the approach is not routable. Quite recently,  
207 net ordering has been incorporated with the SER through proposal of a novel net ordering algorithm in

208 order to reduce the running time Sattar et al. (2017). Recently, we have proposed the solution to this  
209 problem through a network flow approach Ali et al. (2017). We proposed the solution to this problem  
210 through a network flow approach where we introduced two different models; one is based on the links and  
211 called Link based routing, while the other is based on nodes and is called Nodes based routing. They are  
212 introduced to solve SER problem in PCBs through optimization techniques. The models were successful  
213 in routing over small grids but consumed too much time when run over the larger grids.

214 As per our findings, the SER has been explored by these studies and they have provided some good  
215 solutions with various limitations. There are some major issues that still seem to be unresolved and they  
216 include fixed pattern generation and time complexity. Most of these studies are unable to solve problems  
217 like pin blockage and resource under utilization. The studies have used randomized approaches and  
218 heuristic algorithms and optimal solutions are not provided. In this study, we provide an optimal solution  
219 having a time complexity of under a minute along with 99.9% routability for the problem of SER in the  
220 PCBs.

## 221 **PROBLEM FORMULATION**

222 The number of pins in an IC has been increased considerably and the footprint of an IC has shrunk  
223 in recent years making the escape routing problem very difficult. The studies in literature have used  
224 randomized approaches and heuristic algorithms to solve the escape routing problem which have not been  
225 able to reduce time complexity, achieve 99.9% routability, and provide optimal solutions. The problem of  
226 SER has been solved in this study through proposal of an optimal algorithm that not only achieves the  
227 99.9% routability but also consumes very less time and memory to find out the optimal solution.

228 The problem of SER basically boils down to connection of pins of two components. There are many  
229 components on a PCB but there are also many layers available for routing of these components. We solve  
230 this problem by taking two components at a time and producing the best possible routing solution for  
231 them. The routing of two components can be generalized for multiple components. The basic problem is  
232 to escape the pins from inside the pin array of two components and then to connect them by using area  
233 routing. As the size of a pin array is very small and routing resources are very less inside the pin array so  
234 vias cannot be used inside the pin array and all the pins inside pin array must be routed on a same layer.  
235 Once these pins are escaped onto the boundary, different layers can be used for their routing to avoid the  
236 conflicts in area routing.

237 The problem is formulated such that these conflicts in the intermediate area are minimized and least  
238 possible vias are used. The problem can be understood with the help of illustrations. Three ICs can be  
239 seen in the Figure 1, in which some pins are represented with lines inside a hollow circle. Different  
240 patterns of the lines inside hollow circles can be seen. The pins represented by same patterned circles  
241 have to be connected with each other. The pins represented by the simple lines inside the hollow circle  
242 have to be connected with the pins represented by the simple lines inside the hollow circle and the pins  
243 represented by the crossed lines inside the hollow circle have to be connected with the pins represented by  
244 the crossed lines inside the hollow circle. Before connection, these points have to be escaped towards the  
245 boundary first as shown in Figure 2.

246 It can be seen in the Figure 2 that all the pins have been escaped to the boundary of pin arrays without  
247 any conflicts inside the pin array, but there is a conflict route in the intermediate area as shown in Figure 3.  
248 In this situation, one of these routes will be routed on the same layer while the other will be left to be  
249 routed on the second layer as shown in Figure 4. This shows that the basic problem is to escape the pins  
250 from inside of the pin array on the same layer and then connect these escaped pins by using minimum  
251 possible layers in the intermediate area. For this purpose, the pins will be escaped to the boundary in such  
252 a way so that conflicts are minimized in the intermediate area. For the sake of simplicity, routing is done  
253 only on a single layer. So the problem can be stated as:

254 “ To simultaneously escape the pins from inside the pin arrays to the boundaries and connect the escaped  
255 pins while achieving 99.9% routability and minimizing the time required ”

## 256 **NETWORK FLOW APPROACH**

257 The problem formulated in the previous section was to escape the pins from inside the pin arrays to  
258 the boundary of pin arrays and then to connect them in the intermediate area. The components whose

259 pins are to be connected are placed on a board in a manner which is shown in the Figure 5. The square  
260 boxes and remaining points in the Figure 5 represent the ICs and grid points for intermediate area routing  
261 respectively. The Objective is to connect these pins with each other by first escaping them from inside of  
262 the IC simultaneously and then connecting the escaped pins together. This issue is similar to the traffic  
263 flows in a network and hence, it can be mapped to a network flow problem. In the network, a node needs  
264 to communicate with another node and hence there is a need to establish a route between them. Similarly,  
265 the pins in our problem can be considered as nodes of a network the connection between them can be  
266 considered as a route. The purpose is to create a route from one node to another node i.e. connect two pins  
267 with each other. A grid is shown in Figure 5 and this grid is similar to a network grid and there multiple  
268 nodes in that network in a mesh topology.

269 Different types of pins are shown in Figure 6 with the help of circular points where the pins that need  
270 to be connected are shown with a hollow circle and crossed lines inside the circles. The filled circles show  
271 the intermediate nodes through which these pins can be connected to each other. In terms of the network  
272 flow, these cross lined hollow circles are considered as the source and destination nodes while the filled  
273 circles are considered as the intermediate nodes. The objective is to create a route from the source node  
274 towards the destination node by making use of the intermediate nodes. There can be multiple pins that  
275 need to be connected with each other and hence, there can be multiple source-destination pairs and these  
276 pairs are considered as flows in the network.

277 These pairs of pins can be mapped to a network flow. The immediate neighbors of a source and  
278 destination pin are also mapped to the neighboring network nodes. As there is a link between network  
279 nodes, this link is considered as the pin connection. The Table 1 shows how the mapping from the routing  
280 in a PCB to flows in a network is carried out. The terms related to PCB routing are mentioned in the PCB  
281 Routing column and their mapping to network flow is shown in the Network Flow column.

## 282 DUAL MODEL NODE BASED ROUTING

283 The problem of SER and area routing has been solved in two stages with the help of two different integer  
284 linear programs. We name this approach as dual model node based routing. The dual model node based  
285 routing has two stages and these stages are named as local routing and global routing. The pins of pin  
286 arrays are escaped to the boundary of pin arrays in the first stage which is known as local routing. These  
287 escaped pins are then connected with each other in the second stage which is known as global routing.  
288 The concept of local and global routing is explained as follows:

- 289 • Local Routing,
- 290 • Global Routing.

291 This idea of local and global routing of this approach can be understood with the help of Figure 7:

292 **Local Routing** The grid was divided into two parts as it can be seen in the Figure 7. The hollow circles  
293 represent the points that are used in the local routing. Idea is to escape the points that are to be connected  
294 to one of the boundary points. The filled circles on the boundary of hollow circles are the boundary points.  
295 When the desired points have selected a boundary point each, then these boundary points are saved and  
296 their coordinates are passed to the second model through a script. The script checks for those points for  
297 which boundary points are selected and then saves those boundary points as source and destination points  
298 for the second model. This is called as the Local routing.

299 **Global Routing** The work of first stage known as local routing ends after escaping the desired points to  
300 the boundary points. The second model starts working from there and the source and destination boundary  
301 points are connected through second model of this approach. This is called the Global routing. End-to-end  
302 routing with less memory consumption is ensured by these two models together.

## 303 Addressing Link Based and Node Based Routing Issues

304 Memory consumption is the main issue with the link based and node based routing proposed in our  
305 earlier work Ali et al. (2017). There are large number of the variables used in those approaches and as  
306 the number of grid points increase, the memory consumption also increases. These issues are solved  
307 by the dual model node based routing proposed in this paper which not only divides the total memory  
308 consumption between two models known as local routing and global routing but, also ensures the solution

**Algorithm 1** : Local Routing Model

- 
- 1: Decision variable = X [a,b]
  - 2: Number of variables = a x b  
*So in the first model of this approach, the decision variable is:*
  - 3: X [flows, connecting points]  
*For the 10 x 10 grid:*
  - 4: Flows = 1, connecting points =36  
*So the number of variables became:*
  - 5: Variables = flows x connecting points
  - 6: Variables = 1 x 36 = 36
- 

309 with unique routes. For a simple 10 x 10 grid, the number of variables used in the dual model node based  
 310 routing can be calculated by using algorithm 1. Local routing model of the dual model node based routing  
 311 used 36 variables. The number of variables in the global routing model can be calculated a presented in  
 312 algorithm 2.

**Algorithm 2** : Global Routing Model

- 
- 1: Decision variable = X [a,b]
  - 2: Number of variables = a x b  
*So in the second model of this approach, the decision variable is:*
  - 3: X [flows, connecting points]  
*For the 10 x 10 grid:*
  - 4: Flows = 1,connecting points =64  
*So the number of variables became:*
  - 5: Variables = flows x connecting points
  - 6: Variables = 1 x 64 = 64
- 

313 The total number of the variables in both models is 100 which is equal to the number of variables used  
 314 in the node based routing proposed in our previous study Ali et al. (2017) but, these variables are divided  
 315 among two models and are solved separately. Hence there is no issue of memory consumption and the  
 316 end to end route with uniqueness is also ensured by the dual model node based routing. The mathematical  
 317 model and the related terminology of dual model node based routing is explained in the next section.

**Terminology and Mathematical Model**

318 The Table 2 shows the terminology that is helpful in understanding the dual model node based routing.  
 319 The local routing algorithm of the dual model node based routing is explained in algorithm 3 and it uses  
 320 the constraints which are detailed in algorithm 3. A flowchart for algorithm 3 is shown in Supplementary  
 321 Figure 1.  
 322

**Algorithm 3** : Local Routing Model

- 
- 1: The source and destination points must be selected
  - 2: One neighbour of the source and destination point must also be selected
  - 3: If a point is selected, other than source and destination, then two of its neighbors must also be selected
  - 4: Not more than two neighbours of a point must be selected
  - 5: At least one boundary point for each flow must be selected
  - 6: At least one boundary point for the destination of each flow must be selected
  - 7: A point should not be selected for more than one flow
  - 8: Subject to:

$$\min \sum_{(i,j) \in SD} \sum_{(l,m) \in P} X_{i,j,l,m}$$

---

**Constraints for Local Routing Model**

323 The objective function of Local Routing Model is as follows:  
 324

$$325 \quad \min \sum_{(i,j) \in SD(l,m)} \sum_{\epsilon P} X_{i,j,l,m}$$

326 subject to:

$$X_{i,j,i,j} = 1, \forall (i,j) \in LF \quad (1)$$

$$\sum_{(l,m) \in N(LF)} X_{i,j,l,m} = 1, \forall (i,j) \in LF \quad (2)$$

327 The equation 1 makes sure that the starting point for a particular flow is selected. The equation 2  
328 makes sure that one of the neighbors of that starting point must be selected. This is used in order to start  
329 the routing from source and keep it moving towards its neighbor.

330 These equations (1, 2) start the flow but do not make sure that it will continue towards the boundary  
331 points. We have used three equations for that. The equations 3, 4 and 5 ensure the continuity of flow  
332 towards the boundary points and also make sure that a neighbor which is already selected, does not get  
333 selected again. This is used to make sure that flow does not go back towards source.

$$\sum_{(a,b) \in N(l,m)} X_{i,j,a,b}, \forall (i,j) \in LF, \forall (l,m) \in CP - LF \leq 2 \times X_{i,j,l,m} \leq \quad (3)$$

$$\sum_{(c,d) \in N(l,m)} X_{a,b,c,d} \leq 2, \forall (a,b) \in LF, \forall (l,m) \in CP \quad (4)$$

$$\sum_{(l,m) \in BP} X_{i,j,l,m} = 1, \forall (i,j) \in LF \quad (5)$$

334 Now, we have the routed the source points towards the boundary points but we also need an equation  
335 that routes the same destination points to the boundary points. Therefore, we use the same equations for  
336 the destination points which were used for the source points. The equation 6 and equation 7 make sure  
337 that the destination points of the flow are selected along with one of their neighbors. This is done to make  
338 sure that the route starts from destination point and move towards one of its neighbors.

$$X_{a,b,a,b} = 1, \forall (i,j) \in LF, \forall (a,b) \in D(LF) \quad (6)$$

$$\sum_{(l,m) \in N(a,b)} X_{a,b,l,m} = 1, \forall (i,j) \in LF, \forall (a,b) \in D(LF) \quad (7)$$

339 The equations 8, 9 and 10 and 11 ensure the continuity of flow of destination point towards the  
340 boundary points. The previously mentioned equations only selected the destination point and one of the  
341 neighbors but, these equations make sure that an already selected neighbor is not selected again and the  
342 route continues to flow towards the boundary points.

$$2 \times X_{i,j,l,m} \leq \sum_{(a,b) \in N(l,m)} X_{i,j,a,b}, \forall (l,m) \in CP - D(LF), \forall (i,j) \in D(LF) \quad (8)$$

$$\sum_{(c,d) \in N(l,m)} X_{a,b,c,d} \leq 2, \forall (a,b) \in D(LF), \forall (l,m) \in CP \quad (9)$$

$$\sum_{(l,m) \in BP} X_{a,b,l,m} = 1, \forall (a,b) \in D(LF) \quad (10)$$

$$\sum_{(i,j) \in SD} X_{i,j,a,b}, \forall (i,j) \in LF, \forall (a,b) \in CP \quad (11)$$

### 343 Constraints for Global Routing Model

344 The global routing algorithm of the dual model node based routing is explained in algorithm 4 and it uses  
 345 the following objective function and constraints in equations 12 & 13. A flowchart for algorithm 4 is  
 346 shown in Supplementary Figure 2.

---

#### Algorithm 4 : Global Routing Model

---

- 1: The source boundary point must be selected
  - 2: The sum over all the neighboring boundary points of the source boundary point must be less than one
  - 3: If a boundary point is selected, other than source and destination boundary points, then two of its neighboring boundary points must also be selected
  - 4: Not more than two neighbors of a boundary point must be selected
  - 5: The destination boundary point must also be selected
  - 6: A boundary point should not be selected for more than one local flow
- 

347 objective function:

$$348 \max \sum_{(i,j) \in LF} \sum_{(c,d) \in N(startx[i,j],starty[i,j])} Y_{i,j,c,d}$$

349 The local routing model has selected the boundary points for both the source and destination points.  
 350 The local routing model has provided these boundary points to the global routing model. Now, it is the  
 351 responsibility of the global routing model to connect these boundary points together. The first step is to  
 352 select these boundary points and the equations 12 and 13 ensure that the boundary points provided by the  
 353 local routing model are selected in the global routing model.

354 subject to:

$$Y_{i,j,startx[i,j],starty[i,j]} = 1, \forall (i,j) \in LF \quad (12)$$

$$Y_{a,b,endx[a,b],endy[a,b]} = 1, \forall (a,b) \in LF \quad (13)$$

355 After the selection of boundary points, the next step is to select one of the neighbors of the source  
 356 boundary points and then continue the flow towards the destination boundary points. The equations 14, 15  
 357 and 16 are used to ensure the continuity of the flow from source boundary point to destination boundary  
 358 point.

$$\sum_{(c,d) \in N(startx[i,j],starty[i,j])} Y_{a,b,c,d} \leq 1, \forall (a,b) \in LF \quad (14)$$

$$2 \times Y_{a,b,l,m} \leq \sum_{(c,d) \in N(l,m)} Y_{a,b,c,d},$$

$$\forall (a,b) \in LF, \forall (l,m) \in BP - SDBP(LF) \quad (15)$$

$$\sum_{(c,d) \in N(l,m)} Y_{a,b,c,d} \leq 2, \forall (a,b) \in LF, \forall (l,m) \in BP \quad (16)$$

359 There is a possibility that two or more than two flows will select a same point in their route. This  
 360 possibility will cause the crossover and uniqueness of the routes will be affected. These chances of flows  
 361 crossover in the second model is avoided by equation 17.

$$\sum_{(i,j) \in LF} Y_{i,j,a,b} \leq 1, \forall (a,b) \in BP \quad (17)$$

362 The issues of memory consumption and the route uniqueness are solved by the dual model node based  
 363 routing. Apart from that, very small time was consumed to find out the optimal path. In the next section,  
 364 some results are included to support the models proposed.

## 365 RESULTS AND DISCUSSIONS

366 The dual model node based routing is composed of two separate stages. The pins are simultaneously  
 367 escaped to the boundary of the pin arrays in the local routing stage and these escaped pins are connected  
 368 with each other in the global routing stage. A Mathematical Programming Language (AMPL) is used to  
 369 write the script of the algorithm and Gurobi solver is used to solve the algorithm. There are also other  
 370 solvers available apart from Gurobi but Gurobi is the best among all of them in terms of calculation  
 371 time and optimality. The dual model node based routing is based upon Integer Linear Programming  
 372 approach and for Integer Linear Programming approach, Gurobi, Bonmin, and Minos are a few good  
 373 choices. Gurobi has been preferred over the others because of time complexity and integrity issues.

374 The integrality is relaxed by the Minos solver in order to produce optimal results and this loss  
 375 of integrality is not recovered at the output due to which the results are not desirable in some cases.  
 376 Integers are replaced with decimal numbers in some cases which is not feasible for the proposed model  
 377 as integrality must be maintained. Strict integrality is maintained by the Bonmin solver, on the other  
 378 hand, which is also not feasible for the proposed model as too much time is taken to find out the optimal  
 379 solution. The solution of these two problems is provided by Gurobi. The integrality is relaxed by Gurobi  
 380 during the problem solution and it is recovered when the results are generated. In this way, less time is  
 381 consumed to find optimal results with strict integrality. The time consumption of each solver depends  
 382 upon the complexity of the problem. We selected Gurobi through hit and trial because different solvers are  
 383 suitable for different problems. In our case, Gurobi is the best possible selection as it retains the integrity  
 384 and also takes less time as compared to other solvers.

385 These characteristics of Gurobi solver make it a perfect choice for solution of dual model node based  
 386 routing. AMPL is chosen for execution of the algorithms because freedom of high level implementation  
 387 is provided by it. A wide range of optimization problems can be solved with the help of AMPL and same  
 388 syntax is used for declaration of data, model and commands. The local routing and global routing models  
 389 are written in a model file which reads the data from a separate data file. Two models are included in the  
 390 proposed algorithm and these two models are connected together with the help of a script that gathers  
 391 values from the output of the local routing model and provides these values to the input of the global  
 392 routing model.

393 The proposed algorithm was written in AMPL and solved with the help of Gurobi solver. The Gurobi  
 394 solver and AMPL software were run on two different machines in order to have a comparison of algorithm  
 395 running time on different machines. The first machine used for algorithm execution was an Intel Core 2  
 396 Duo PC with a processor of 2.10 GHz and a RAM of 2GB. The other machine used for the execution of  
 397 the algorithm was NEOS server which can be accessed on-line. NEOS server consisted of a 2.8GHz (12

398 cores) CPU - 2x Intel Xeon X5660, 64GB RAM, and 2x 500GB/2TB SATA drives disk. The purpose of  
399 using these two machines was to show that the proposed algorithm can be used by PC users as well as  
400 server operators. We have mentioned specifications of both the machines so that anyone can easily use  
401 the same specifications and check the validity of results and also compare the results with their proposed  
402 solution. There was definitely a difference between time consumed by these two machines which is  
403 mentioned in the next section.

404 The dual model node based routing is tested on three grids of different sizes. These three grids were  
405 of small, medium and large sizes respectively. The intention was to run the proposed model on grids of  
406 different sizes so that efficiency of model could be claimed for all types of grids. The specifications of  
407 three grids against which the model was tested are as follows:

- 408 • Small Grid,
- 409 • Medium Grid,
- 410 • Large Grid.

#### 411 **Small Grid**

412 The first grid has a size of 20x20 and according to the dual model node based routing, this grid is divided  
413 into two parts. These two parts are solved with the local routing model first and then with the global  
414 routing model. The first part contains two 13x6 grids which are used for escaping the points to the  
415 boundary and this is solved by the local routing model. The second part contains the remaining points  
416 which are used for the area routing and it is solved by the global routing model. A total of 60 pins have  
417 been escaped through this grid in 0.4 seconds when solved on a Intel core 2 duo PC and 0.32 seconds  
418 when solved through NEOS server on-line. The escaped points in the 20 X 20 grid are shown in the  
419 Figure 8. These escaped pins are connected through the second model as shown in Figure 9.

420 It can be seen that not all the escaped pins are connected by the global routing model. It is because of  
421 the reason that not enough routing resources are available to route all these escaped pins on a single layer.  
422 There are two solutions to this, either the remaining escaped pins can be routed on other layers or the grid  
423 can be expanded sideways in order to route all the escaped pins on a single layer. The second solution  
424 is not feasible because the solver used for solving this problem is an academic version of Gurobi which  
425 cannot handle more than a specified number of constraints. The commercial version of Gurobi needs to be  
426 purchased in order to solve the larger grid for the area routing problem. Therefore, it has been shown with  
427 the help of a relatively smaller grid that area routing can be done with the help of the proposed model.  
428 The proposed dual model node based routing is equally good for area routing of the large grids.

#### 429 **Medium Grid**

430 The results of the dual model node based routing have also been compared with a study in literature Wu  
431 and Wong (2013). The solver used by Wu and Wong (2013) is min-cost flow solver CS2. Although,  
432 the solver used by them is different from our solver but the choice of a solver depends upon the model  
433 and in our case, Gurobi proved to be the best solver in all cases. In Wu and Wong (2013), network flow  
434 model has been proposed for escaping the pins to the boundaries and few results have been obtained in  
435 this study using industrial data. In one of their cases, 42 pins were escaped in a grid of 11 x 27 in 0.08  
436 seconds. We designed a 30x30 grid in which the first model was a 11 x 27 grid similar to the study Wu  
437 and Wong (2013). We were able to escape 68 pins in the same grid within 0.12 seconds through NEOS  
438 server. This shows that all the desired pins have been escaped to the boundary. The memory used for the  
439 processing was 68.48 MB. The memory consumption is very less and the time taken to solve the problem  
440 of routing is also quite less. The results of escaped pins are shown in Figure 10. After this, the global  
441 routing model will connect these escaped pins but it has not been shown because of the reason mentioned  
442 in the previous sub section that the academic version of the gurobi cannot handle more than a specified  
443 number of constraints. If we use another solver instead of Gurobi, we would not be able to get optimal  
444 results. Also, we do not have enough resources to buy the commercial version of Gurobi. We have already  
445 tested the global routing model for the smaller cases in order to show that our model works perfectly well.

#### 446 **Large Grid**

447 The large grid taken to evaluate the dual model node based routing is a 50x50 grid. The results have been  
448 compared with another case of the same study Wu and Wong (2013). In this case, 86 and 112 pins were  
449 escaped in a grid of 17 x 34 in 0.16 seconds. We designed a 50x50 grid in which the local routing model

450 contained 17 x 34 grid similar to this case in the study Wu and Wong (2013). We were able to escape  
451 112 pins in the same grid within 0.02 seconds through NEOS server. This shows that the all the desired  
452 pins are escaped to the boundary within a minimal time. The memory consumed during processing was  
453 190.6 MB which is also quite less. The number of escaped pins can also be increased by changing our  
454 grid topology a bit which is out of scope of this work. The results of escaped pins are shown in Figure 11.

455 The case used for comparison uses only a 17 x 34 grid and we use a 50 x 50 grid in which we escape  
456 112 points using an internal grid of 17 x 34. If we use only a grid of 17 x 34 and run first model only, then  
457 we can get results in half time i.e. 0.01 seconds and memory consumption is also reduced to 97.05 MB.  
458 This is a considerable reduction in time as compared to the time (0.16seconds) taken by the case taken in  
459 the compared study. The results of area routing in both the above mentioned cases have not been obtained  
460 due to the limitations of the academic version of the Gurobi solver. The results for small, medium, and  
461 large grid are shown in Table 3. It can be seen that as the number of pins increases, our proposed model  
462 takes less and less time as compared to Wu and Wong (2013). This also shows the scalability of our  
463 model. As the number of pins is increasing, our model is taking less time and hence, it would still be  
464 suitable if number of pins is scaled up. We could not test all the cases provided in Wu and Wong (2013)  
465 because of academic solver's limitations and relevancy. We choose the most relevant cases from Wu and  
466 Wong (2013) for comparison.

467 Table 3 shows that the proposed dual model node based routing method is great in terms of routability  
468 and it also takes very less time and memory to provide the routing solution. We have compared our  
469 model's efficacy with state-of-the-art models and our model outperforms state-of-the-art in the terms of  
470 time consumed. The memory consumed by the proposed dual model node based routing method is also  
471 considerably small which shows that no high end machines are required to run this model.

## 472 CONCLUSION

473 This work address two problem at the same that includes simultaneous escape routing and area routing  
474 in PCB. Main contributions of this research is the mapping of PCB routing problem to network flow  
475 problem and proposal of two algorithms for SER and area routing using integer linear programs. This  
476 work also links the local and global routing algorithms in order to achieve the end-to-end routing on a  
477 PCB. Proposed algorithms are efficient in terms of routing and time consumption as they outperform  
478 the existing algorithms and achieve 99.9% routability. Currently, we are working to propose a blend of  
479 ordered escape routing with the SER for further optimizing routability and improve time consumption.  
480 We also aspire to scale this algorithm for dual layer and multi-layer PCBs.

## 481 AUTHOR CONTRIBUTIONS

- 482 • Asad Ali wrote the initial draft, devised the methodology and also did the software development for  
483 design and analysis of the proposed solution.
- 484 • Asad Ali and Anjum Naveed conceptualize the solution, did formal analysis. Anjum Naveed also  
485 did the validation and supervised this work.
- 486 • Muhammad Zeeshan reviewed and editing the manuscript, did the validation and also finalized and  
487 approved the final draft.

Mapping Table

1

---

<b>PCB Routing</b>	<b>Network Flow</b>
Pins	Network Nodes
Pins that need to be connected	Source node and destination node
pin-pin pair	Network flows
Connection of two neighboring pins	Network Links
Layers	Channels

---

**Table 2** (on next page)

Terminology used in the mathematical models of the dual model node based routing

<b>Term</b>	<b>Meaning</b>
LF	The set which includes sources of local points in grid
N(LF)	The set which includes neighboring points of LF points
N(P)	The set which includes neighbors of all P points
SD	The set which includes source and destination points of Local flows
SDBP	The set which includes source and destination boundary points of Local flows
D(LF)	The set which includes the destination flows
P	The set which includes all grid points
BP	The set which includes all grid boundary points
N(BP)	The set which includes boundary points neighbors
CP	The set which includes connections of points in LF
startx	The parameter which has the x coordinate of boundary points selected as Local Flow's source
starty	The parameter which has the y coordinate of boundary points selected as Local Flow's source
endx	The parameter which has the x coordinate of boundary points selected as Local Flow's destination
endy	The parameter which has the y coordinate of boundary points selected as Local Flow's destination
X[flows, points]	The binary decision variable for selection of a flow
Y[flows, edges]	The binary decision variable for selection of a boundary point for a flow
