Optimizing global connectivity in spatial networks, either through rewiring or adding edges, can increase the flow of information and increase the resilience of the network to failures. Yet, rewiring is not feasible for systems with fixed edges and optimizing global connectivity may not result in optimal local connectivity in systems where that is wanted. We describe the local network connectivity optimization problem, where costly edges are added to a systems with an established and fixed edge network to increase connectivity to a specific location, such as in transportation and telecommunication systems. Solutions to this problem maximize the number of nodes within a given distance to a focal node in the network while they minimize the number and length of additional connections. We compare several heuristics applied to random networks, including two novel planar random networks that are useful for spatial network simulation research, a real-world transportation case study, and a set of real-world social network data. Across network types, significant variation between nodal characteristics and the optimal connections was observed. The characteristics along with the computational costs of the search for optimal solutions highlights the need of prescribing effective heuristics. We offer a novel formulation of the genetic algorithm, which outperforms existing techniques. We describe how this heuristic can be applied to other combinatorial and dynamic problems.

## 12 **ABSTRACT**

13 Optimizing global connectivity in spatial networks, either through rewiring or adding edges, can increase  
14 the flow of information and increase the resilience of the network to failures. Yet, rewiring is not feasible  
15 for systems with fixed edges and optimizing global connectivity may not result in optimal local connectivity  
16 in systems where that is wanted. We describe the local network connectivity optimization problem,  
17 where costly edges are added to a systems with an established and fixed edge network to increase  
18 connectivity to a specific location, such as in transportation and telecommunication systems. Solutions  
19 to this problem maximize the number of nodes within a given distance to a focal node in the network  
20 while they minimize the number and length of additional connections. We compare several heuristics  
21 applied to random networks, including two novel planar random networks that are useful for spatial  
22 network simulation research, a real-world transportation case study, and a set of real-world social  
23 network data. Across network types, significant variation between nodal characteristics and the optimal  
24 connections was observed. The characteristics along with the computational costs of the search for  
25 optimal solutions highlights the need of prescribing effective heuristics. We offer a novel formulation of  
26 the genetic algorithm, which outperforms existing techniques. We describe how this heuristic can be  
27 applied to other combinatorial and dynamic problems.

## 28 **INTRODUCTION**

29 Spatial networks have become more popular as the interest in networks has spread into more fields and  
30 spatial data, and the computational power and methods to analyze it, have become more accessible.  
31 In terms of analysis, spatial network optimization has been at the forefront and focused on increasing  
32 network connectivity and information flow (Schrijver, 2002; Wu et al., 2004). Heuristics have been  
33 developed to rearrange existing networks or creating new ones that optimize the topology of the network  
34 for synchronizability (Khafa and Jalili, 2019). Several effective methods have also been developed to  
35 add new edges to a network that minimize the average shortest path distance (Meyerson and Tagiku,  
36 2009), minimize the network diameter (Demaine and Zadimoghaddam, 2010), or maximize the network's  
37 centrality (Jiang et al., 2011) or connectivity (Alenazi et al., 2014).

38 While this optimization of spatial networks' global characteristics, optimizing local existing network  
39 connectivity around a specific node or location with the introduction of costly new edges has not  
40 been explored and yet is important in several domains. For example, increasing an existing network's  
41 connectivity around a focal node while minimizing the costs associated with the number and lengths  
42 of additional connections is essential in network layout planning for telecommunications and computer  
43 systems (Resende and Pardalos, 2006; Donoso and Fabregat, 2007) and increasing or slowing the spread of  
44 information or diseases in social networks (Gavrillets et al., 2016; Eubank et al., 2004). This local network

connectivity problem is particularly important with transportation planning in urban environments, where the weights of the network edges can be physical distances or riderships and future street connections or transportation lines can be significantly costly and impact flow to established facilities. For example, planners can optimize thoroughfare connectivity around schools to foster student walking and biking while reducing busing costs (Auerbach et al., 2021) and increase accessibility and patient travel time to health care facilities (Branas et al., 2005).

The search for new edges that maximize connectivity to a focal node and minimize the costs of these new edges is not well understood and this search for optimal solutions can become costly when networks are large and complex. To fill this knowledge gap, we compare a set of heuristics to optimize local network connectivity applied to real-world networks and randomly generated ones. These heuristics are drawn from Mladenović et al. (2007) review of combinatorial heuristics and from location models that include a spatial component (Brimberg and Hodgson, 2011). We also offer a genetic algorithm with a novel chromosome formulation where the genes are not properties of a specific variable but weights for the probability to move in a given dimension across the solution space.

These optimization heuristics are then applied to randomly generated networks that vary in complexity and size to evaluate their efficacy in finding the optimal new connections that maximize local connectivity. Included in this set of random graphs we provide two novel formulations of random planar networks based on the Voronoi diagram and the Delaunay triangulation. To complement the random network analysis, the network connectivity optimization methods are also applied to two real-world case studies, one from urban transportation planning and another from social network analysis. In this study, we show that optimization heuristics are preferred for the analysis and practice due to the nonlinearity of the solution space and the optimal solution's dependence on nodal characteristics, such as distance to the focal node. The novel genetic algorithm outperformed the other heuristics as it was able to move from suboptimal solutions and explore distance solutions quicker. This is important as researchers and engineers are working with networks or growing complexity and size.

The organization of this paper is as follows. The next section describes the formulation of the connectivity problem in more detail, the local search methodology, and the optimization heuristics (see Appendix A for the specific pseudocode of the optimization algorithms). This is followed by a section that details the data used for the study including descriptions of the random networks, the transportation case study street networks, and the social network data. Results of the heuristics applied to the random networks and the case studies are then presented. The paper concludes with a detailed discussion of these heuristic results, the further implications of these techniques for urban transportation planning, and future work for this avenue of research.

## METHODS AND DATA

### Formulation of the Network Connectivity Problem

For the description of the optimization methodology the following nomenclature will be used (see Table 1). In connectivity optimization, network nodes are first segmented and assigned to 'close' and 'distant' sets by a chosen threshold distance  $D$  from the network's focal node  $F$ . The number of nodes  $v$  in a network is  $N$ , and nodes are separated into two sets based on their shortest network path distances to the focal node,  $d(v, F)$ . The nodes that are within this distance are assigned to the 'close' set,  $N_C \subset N$ , i.e.,  $v \in N_C$  if  $d(v, F) \leq D$  and  $F \in N_C$  (see Figure 1 (A)). The nodes that are outside the threshold shortest network path distance to the focal node,  $D$ , are assigned to the 'distant' set,  $N_D \subset N$ , i.e.,  $v \in N_D$  if  $d(v, F) > D$ . When a new connection is added to the network, the shortest path distance from each distant node to the focal node is recalculated. If there are any distant nodes that are now within the threshold distance to the focal node they are assigned to the new set  $N_{i,j}^C$ . For example, if a new connection is established between distant node  $i$  and close node  $j$ , then  $k \in N_{i,j}^C$  if  $k \in N_D$  and  $d(k, i) + d(i, j) + d(j, F) \leq D$  (Figure 1 (C)). The benefit of this new connection is  $B(i, j)$  and the cost associated with the new connection is  $C(i, j)$ . The optimal solution is the solution with the greatest benefit, or number of new nodes now within the

distance to the focal node which can be expressed as the bi-objective function

$$\begin{aligned} O^* &= \max(B(i, j)) + \min(C(i, j)) \\ \text{s.t. } \sum_i v_i &= 1, i \in N_C \\ \sum_j v_j &= 1, j \in N_D \end{aligned} \quad (1)$$

where benefits dominate costs. For example, if  $B(i, j) = B(m, n)$  and  $C(i, j) < C(m, n)$ , then the optimal additional edge is between  $i$  and  $j$ . For nondominated solutions, we select the solution that minimizes the distance to the so-called ideal point. The ideal point represents the solution that simultaneously maximizes the benefit and minimizes the cost. For the analysis in this paper the formulation of the objective function is as follows. For a new edge between  $i$  and  $j$  the number of nodes in  $N_{i,j}^C$  set is the benefit of this new connection,  $B(i, j) = |N_{i,j}^C|$ , and the cost of the new connection is the length of the edge  $C(i, j) = d(i, j)$ . Therefore,

$$\begin{aligned} O^* &= \max(|N_{i,j}^C|) + \min(d(i, j)) \\ \text{s.t. } \sum_i v_i &= 1, i \in N_C \\ \sum_j v_j &= 1, j \in N_D \end{aligned} \quad (2)$$

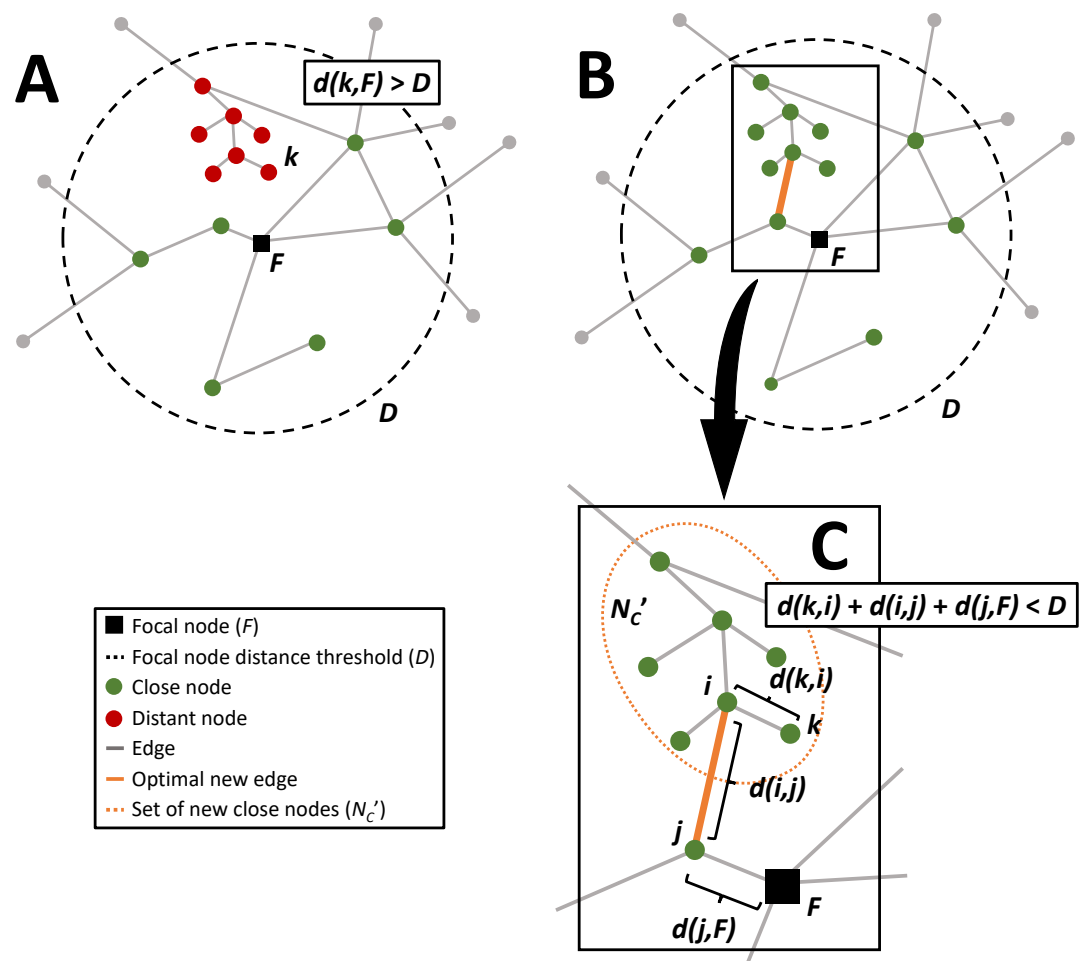

80 Most of the heuristics presented below are dependent on the number of iterations ( $t$ ) and terminate when  
81 the solutions converge,  $O^t = O^{t-1}$ , or the solution does not improve,  $O^t < O^{t-1}$ .

## 82 Local Search Methodology

83 For a network of size  $N$  the number of new connections to evaluate has an upper bound of  $N^2/4$ , therefore  
84 heuristics may be employed to identify (nearly) optimal solutions quicker than an exhaustive search as  
85 networks get larger. These optimization algorithms require a search space to explore and using nodal  
86 characteristics we create such a multidimensional solution space (see Table 2). These nodal characteristics  
87 are explored to find the critical network properties for connectivity optimization and their impact on the  
88 performance in finding the optimal solution. As several nodes in a network can potentially have the same  
89 nodal characteristic values the local searches include a random shuffling routine. In detail, the following  
90 individual node characteristics were used to create the dimensions of the solution space: (i) distance to  
91 the focal node, (ii) degree centrality, (iii) closeness centrality, (iv) betweenness centrality, (v) eigenvector  
92 centrality, (vi) pagerank centrality, (vii) weighted clustering coefficient, and (viii) the neighbor nodes  
93 directly connected to the node. Nodes were sorted by their distance to the focal node and moving in  
94 this solution dimension may result in lower connectivity length costs but may not maximize the number  
95 of nodes ultimately connected to the focal node. In contrast, sorting nodes by their centrality, i.e., the  
96 importance of the node, could result in maximizing the number of nodes within the specified distance to  
97 the focal node but with the possibility of higher connectivity length costs compared to selecting nodes  
98 by other characteristics. To avoid these two extreme possibilities, several commonly used measures  
99 of centrality are explored: degree, the number of edges incident to a node; closeness centrality, the  
100 average length of the shortest path between the node and all other nodes in the network (Bavelas, 1950);  
101 betweenness centrality, the frequency of a node included in the shortest paths between all other node pairs  
102 (Freeman, 1977); eigenvector centrality, which is a relative sorting of nodes such that nodes with high  
103 values are connected to other nodes with high values (Newman, 2008); and pagerank centrality, a variant  
104 of eigenvector centrality that sorts nodes based on their probability of being connected to a randomly  
105 selected node and which is commonly used in web-page rankings (Brin and Page, 1998). The weighted  
106 clustering coefficient of a node is the count of the triplets in the neighborhood of the node and accounts  
107 for the weights of the edges times the maximum possible number of triplets that could occur (Barrat et al.,  
108 2004). The weights used here are the spatial distances between nodes  $w_{ij} = d(i, j)$ . The nodes that were  
109 directly connected to the node under evaluation were also used.

## 110 Network Connectivity Optimization Heuristics

111 The following techniques were implemented for the network connectivity optimization study from their  
112 extensive use in optimization: hill climbing with random restart (Russell and Norvig, 2004); stochastic

**Figure 1.** Diagram of the sequence of the network connectivity optimization problem. The close nodes that are within a threshold network distance (orange dashed circle) from the focal node (black square) are colored green, distant nodes that could be within the threshold network distance with additional edges are colored red, and the gray distant nodes are outside the threshold distance regardless of any additional connections. Figure (A) is an example graph, (B) shows the same graph with the optimal new connection that maximizes the number of additional nodes within the threshold network distance and minimizes the length of the new connection, and the inset (C) highlights this optimal connection, between nodes  $i$  and  $j$ .

hill climbing (Greiner, 1992); hill climbing with a variable neighborhood search (Mladenović and Hansen, 1997); simulated annealing, which has a history of applications in graph problems (Kirkpatrick et al., 1983; Johnson et al., 1989; Kirkpatrick, 1984); and genetic algorithms, which has been successfully used for combinatorial optimization (Anderson and Ferris, 1994; Jaramillo et al., 2002). A Tabu heuristic was not employed as it has been observed to be an inferior method for multi-objective optimization problems compared to simulated annealing and genetic algorithms (Golden and Skiscim, 1986; Kim et al., 2016). Parameter selection was simplified for easy comparison of the methods (see the Supplemental Information for the algorithms). To ensure that the heuristics did not converge on suboptimal solutions due to the initial starting values, random restart, i.e., randomly selecting initial nodes to avoid local optima and running the routine until the optimal solution is found, was used.

**Exhaustive search (ES).** The exhaustive search calculates the solution for every pair of distant and close nodes for a network (see Algorithm 1 in the Supplemental Information). While this approach ensures that the optimal edges are found, as the number of nodes increases and therefore the number of possible connections between close and distant nodes increases, it can become computationally expensive and timely to implement. Since the results of ES provide the optimal solution, the times it takes to find

128 evaluate all solutions are used to benchmark the other heuristics.

**Hill climbing (HC).** The solution space was observed to be hilly from the exhaustive search results, so several modifications were introduced to the hill climbing technique to avoid getting stuck in suboptimal solutions (Algorithm 2 in the Supplemental Information). A stochastic hill climbing (**HCS**), an advanced search method based on HC, routine is also explored where the selection of nodes for the next iteration is randomly picked with

$$\text{probability}(i, j) = \frac{O(i, j)}{\sum_{(m, n)} O(m, n)}, \quad (3)$$

which terminates when an improved solution is no longer found (Algorithm 3 in the Supplemental Information). A hill climbing algorithm is coupled with a variable neighborhood (**HCVN**) where the size of the neighborhood starts with the nearest neighbors ( $\eta = 1$ ) and is updated as follows:

$$\eta = \begin{cases} 1 & \text{if } O' > O^{t-1} \\ \eta + 1 & \text{if } O' \leq O^{t-1} \end{cases}, \quad (4)$$

129 and the HCVN method terminates after  $n_{max}$  is reached (Algorithm 4 in the Supplemental Information).

**Simulated annealing (SA).** As a meta-heuristic approach, the simulated annealing method randomly selects an initial solution from the solution space to avoid entrapment in a local optima. At each iteration, the heuristic evaluates the neighboring solutions and if it does not find an improved solution, it moves to a new solution with the following probability:

$$\text{probability}(i, j) = \exp\left(-\frac{O^{t-1} - O(i, j)}{t}\right). \quad (5)$$

130 The distance of the move decreases with the number of iterations until a better solution is no longer found  
131 (Algorithm 5 in the Supplemental Information).

**Genetic algorithm (GA).** The genetic algorithm begins with a population of  $P$  randomly selected solutions with a set of chromosomes composed of genes which represent the weights of selecting a neighbor and are all initialized to unity (Algorithm 6 in the Supplemental Information). During each iteration of the method, solution scores (fitnesses) are computed by

$$f(i, j) = \frac{O(i, j)}{\sum_{(m, n)} O(m, n)}, \quad (6)$$

and a new generation of solutions are selected based on the following probability condition

$$\text{probability}(i, j) = \frac{s * f(i, j) + (1 - s)}{\sum_{(m, n)} (s * f(m, n) + (1 - s))}, \quad (7)$$

where  $s$  is the selection coefficient. Weak selection,  $s \ll 1$ , is used to ensure that random mutations impact solution frequency. Crossover is conducted by alternating the weights for the offspring from each parent, also known as cycle crossover (Oliver et al., 1987). Mutations are introduced at a low rate  $\mu \ll 1$  for each gene and increase the nodal characteristic selection weight by one. The probability that characteristic  $m$  is used to find a neighbor for node  $i$  is given by

$$\text{probability}(\text{characteristic}) = \frac{\text{gene}(i, m)}{\sum_k \text{gene}(i, k) / K}, \quad (8)$$

132 where  $K$  is the total number of nodal characteristics. This formulation ensures that the nodal characteristics  
133 that improve the solution increase in weight which results in a greater probability they will be selected  
134 for neighborhood exploration, and ultimately reduces the size of the neighborhood search. Among these  
135 methods, the genetic algorithm presented here introduces a novel chromosome formulation where the  
136 genes are not properties of a specific variable but weights for the probability to move in a given direction  
137 in the solution space. This allows the method to occasionally explore different nodal characteristics (at  
138 mutation rate  $\mu$ ) while conducting a local neighborhood search.

### 139 Simulated Data: Random Networks

140 To test the efficacy of these optimization heuristics in finding the optimal new network connections  
 141 they were applied to randomly generated networks that vary in complexity and size. Several types of  
 142 random graph networks were generated to analyze the efficacy of the optimization heuristics for systems  
 143 with different topologies which are generally representative of naturally occurring and built systems: (1)  
 144 Erdős-Rényi networks, (2) Watts-Strogatz networks, (3) Barabási and Albert networks, (4) Klemm and  
 145 Eguíllez networks, (5) Delaunay triangulation networks, and (6) Voronoi diagrams. Erdős-Rényi random  
 146 networks are constructed by randomly creating connection between pairs of nodes with a probability  
 147 (Erdős and Rényi, 1959). These networks, even though they have random connections, consistently have  
 148 short average path lengths and irregular connections, both of which are well found in natural systems.  
 149 The Watts-Strogatz networks also have random connections but the networks also form clusters, another  
 150 feature commonly found in real-world networks (Watts and Strogatz, 1998). The Barabási-Albert model  
 151 produces random structures with a small number of highly connected nodes, 'hubs', which are observed in  
 152 numerous types of networks (Barabási and Albert, 1999; Albert and Barabási, 2002). Klemm and Eguíllez  
 153 networks have random connections, clusters, and hubs (Klemm and Eguíllez, 2002). See Supplemental  
 154 Information Figure S.1 (A) – (D) and Prettejohn et al. (2011) for the algorithms used to generate these  
 155 networks.

We also introduce two novel types of random planar network versions of the Voronoi diagram and  
 the Delaunay triangulation (Supplemental Information Figure S.1 (E) and (F)). Planarity is particularly  
 important in many fields and networks generated from Voronoi diagrams and Delaunay triangles have been  
 used in spatial health epidemiology (Johnson, 2007), transportation flow problems (Steffen and Seyfried,  
 2010; Pablo-Martí and Sánchez, 2017), terrain surface modeling (Floriani et al., 1985), telecommunica-  
 tions (Meguerdichian et al., 2001), computer networks design (Liebeherr and Nahas, 2001), and hazard  
 avoidance systems in autonomous vehicles (Anderson et al., 2012). Delaunay triangulation maximizes the  
 minimum angles between three nodes to generate planar graphs with consistent network characteristics  
 while Voronoi diagrams, the dual of a Delaunay triangulation, are composed of points and cells such that  
 each cell is closer to its point than any other point (Delaunay, 1934). To modify these edges are removed  
 from network nodes randomly based on their distance from the focal node with probability

$$p_R \cdot \frac{\max(d(i, F), d(j, F))}{\max_k d(k, F)}, \quad (9)$$

156 where  $p_R$  is the removal probability and weighted by the normalized edge distance from the focal node.  
 157 When edges are randomly removed from the connected Delaunay network or Voronoi network, with  
 158 weights given by node distance from a focal node, these networks display some of the properties similarly  
 159 found in the networks mentioned above, such as complexity and randomness. Yet, these networks have  
 160 the added component of being planar and having edge weights that can be framed as physical distances.

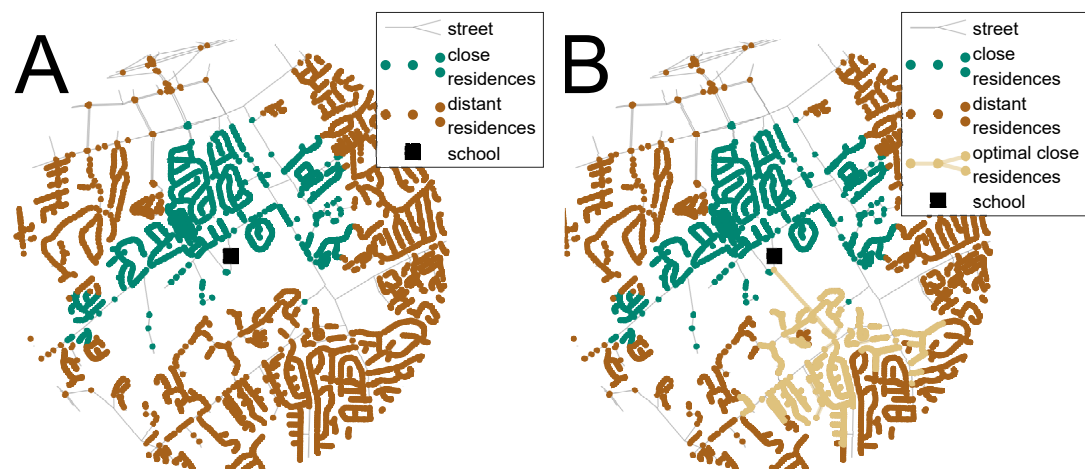

161 To compare the efficacy of different optimization methods for different network topologies, identifying  
 162 the best set of parameters are critical. Parameter values were selected for each type of random network to  
 163 ensure network complexity (Supplemental Information Table S.6 summarizes the parameters which were  
 164 used in the analysis). Variation in network size was also explored and the most connected node in each  
 165 network was selected as the focal node. Uniformly randomly generated edge weights in [0,1] were used  
 166 for the network distances and the threshold distance was set to ensure that half of the nodes were initially  
 167 within the distance to the focal node. The costs and benefits were normalized using the ranges from the  
 168 exhaustive search routine as a benchmark to compare the results from the different optimization methods.

### 169 Empirical Data: Transportation Case Study

170 To complement the random network analysis, the network connectivity optimization methods were applied  
 171 to a study of urban transportation planning. Network connectivity optimization methods were used to  
 172 evaluate the potential costs and benefits of increased thoroughfare connectivity for student walking or  
 173 biking to school. It is assumed that expanding the connectivity around a school would allow for more  
 174 households, and students, to be included within the walking distance to the school. If more students  
 175 actively commute to school, this reduces the busing costs for the school system and increases the health  
 176 and academic achievement of the students (Centers for Disease Control and Prevention, 2010). Yet, streets  
 177 have associated land, construction, and maintenance costs that are primarily dependent on their length.

178 Networks composed of street edges and residence nodes around several schools from a representative  
 179 US school system were used for the analysis. Ten suburban and rural schools from Knox County, TN, were

selected for the analysis, including seven elementary and three middle, that would benefit the most from increased thoroughfare connectivity, i.e., had the most students within the Euclidean walking distance but not the network distance to the school (characteristics of these schools are provided in the Supplemental Information Table S.3). Urban schools were not used since the street connectivity around the schools was significantly high and the from additional thoroughfares would be low. Residential parcels and street networks were provided by the Knoxville-Knox County Metropolitan Planning Commission and the residential parcels were converted to nodes and placed on the nearest street edge. The residences within 1 mile and 1.5 miles, for the elementary schools and the middle schools respectively, are considered close nodes while the nodes outside of these distances were classified as distant nodes (see Figure 2). The school networks do not generally display the characteristics of complex network: they had low average degree, large path lengths, and were not efficient, yet they did have power distributions of connectivity with few intersections having a large number of street connections (see Supplemental Information Table S.3). The networks were evaluated with each optimization method to maximize the number or close residences connected to the school and minimize the distance of the new thoroughfare. The costs and benefits of these street connections were normalized using the ranges from the exhaustive search routine as a benchmark to compare the results from the different optimization methods.

**Figure 2.** Results of the transportation case study used for the analysis. A network of streets and residences around a school is shown in (A) and with the optimal new walking connection in (B). The red nodes represent the distant residences, i.e., the residences within the 1-mile Euclidean walking distance to the school but not the 1-mile street network walking distance, the green nodes are the close residences within the street network school walking distance, and the black square represents the school. The orange line is the optimal new walking connection that maximizes the number of additional residences (orange nodes) and minimizes the length of the new connection.

## Empirical Data: Social Network Analysis

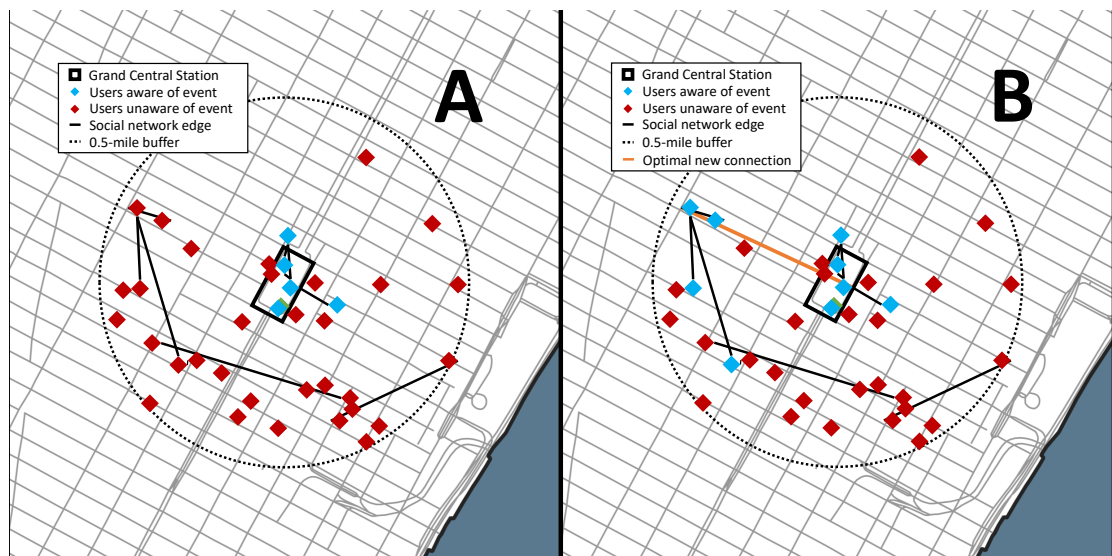

The topology of a network and the management of its system can improve information flow and have been shown to help counter the negative effects of social and environmental crises (Helbing et al., 2015). Specifically, increased social network connectivity can reduce the time information spreads among its members. For example, quickly notifying those nearby and unaware of an active shooter event can save lives. Using a set of social network data coupled with location data, we evaluated the heuristics to optimize social network connectivity for those nearby a specific location.

The data set used for this analysis was from Gowalla, a location-based social networking website where users share their locations by checking-in, and this data set was collected and published by Cho et al. (2011). This social network is undirected and consists of 196,591 nodes (members) and 950,327 edges (social connections). There is a total of 6,442,890 check-ins of these members over the period of February 2009 to October 2010 (network characteristics are provided in the Supplemental Information Table S.4). For the analysis we simulated 100 crisis incidents at a highly populated urban place, Grand

Central Terminal in New York City (NY). Grand Central Terminal was selected as the location of the simulated events as it is a major transportation hub located in the center of the city that serves over a million commuters and visitors daily. New York City is also a major metropolis with tens of thousands of Gowalla users present in the data set and the city has a history of incidents, such as terror attacks. Ten dates were selected at random and for each date ten times were randomly selected between 1200 and 1800 local to simulate a crisis event (see Figure 3).

The social network problem was formulated such that an event occurred at the location (Grand Central Station) and members who were within 0.5-miles of the event should be notified. The members within Grand Central Station are automatically notified of the event whereas those outside can be notified through their online social network if a member in their network is aware. The event is considered to be serious enough that those members aware of it will share the information on the social network. New connections are evaluated based on their number of additional nearby members who become aware of the event.

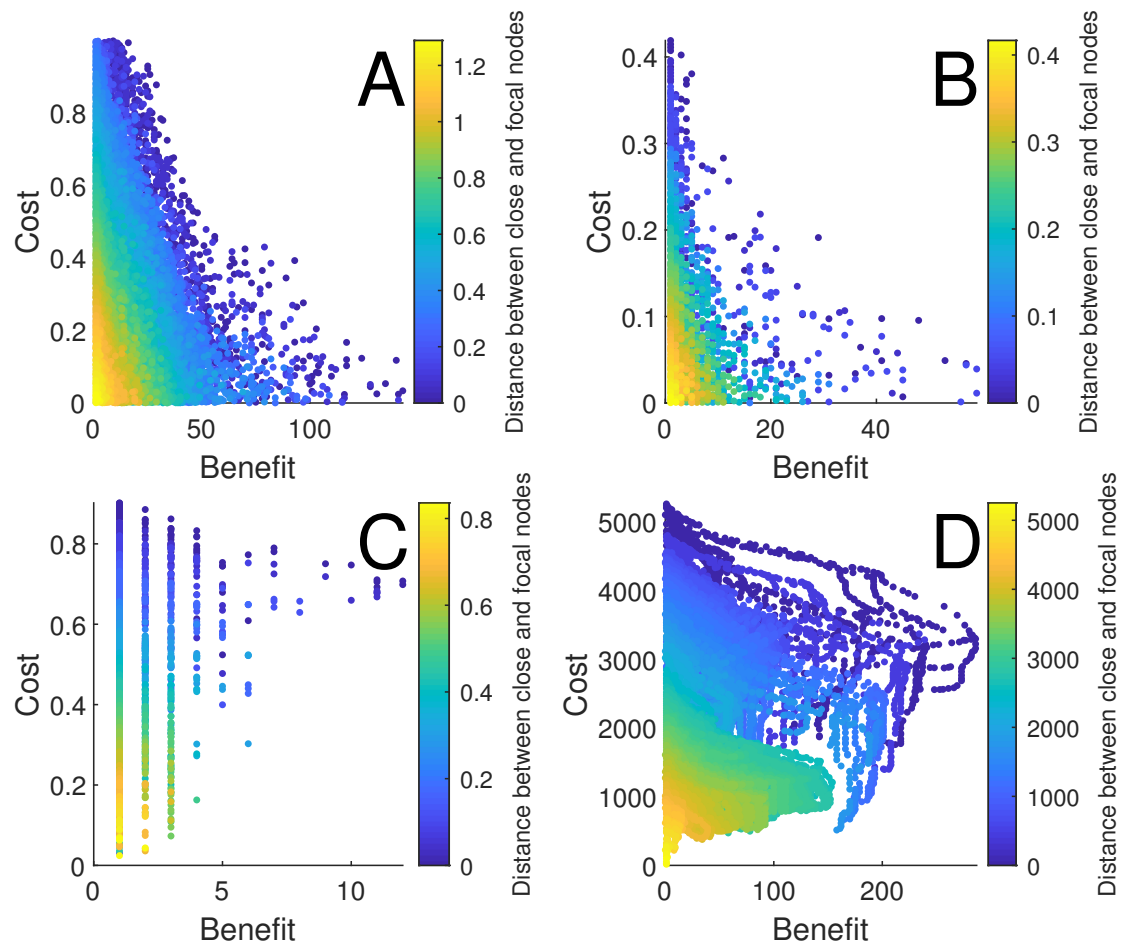

**Figure 3.** Results of the Gowalla social network case study used for the analysis. For simplicity the network shown is the users with a check-in within 1 hour prior to the event and nearby (within 0.5-mile) the event location, Grand Central Station (NYC). (A) the network prior during the event and (B) with the optimal connection. The red nodes represent the users within 0.5-mile who are unaware of the event, the green nodes are the users aware of the event, the black line represents. The orange line is the optimal new social network connection that maximizes the number of additional nearby users aware of the event.

## PERFORMANCE OF THE ALGORITHMS

Several findings are worthy to note regarding the performance of heuristic algorithms used in the analysis. First, there were consistent nonlinear relationships between the nodal characteristics and the quality of the solutions for each type of random network and the school networks (see Figure 4). There was also significant variation for which nodal characteristics were correlated with the quality of the solution across networks (see Table 3). Among those, the distance between the close node and the focal node and the distance between the distant node and the close node were most often highly correlated with the quality of the solution across networks. The centrality measures were inconsistently related to the solution quality for the random networks yet were related to the optimal solutions for the social networks.

The results of the termination times and the optimal solutions deviations from the optimization heuristics applied to the random networks are summarized in Figure 5 and Supplemental Information Figures S.1 and S.2. The hill climbing method was consistently faster for all of the networks, yet had the largest cost and benefit deviations. Simulated annealing and the genetic algorithm had similar termination times, but the genetic algorithm was consistently superior to all of the other methods in approaching the optimal solution. The results from the application of the optimization heuristics applied to the ten school networks are shown in Figure 5 (E) and (F). The times to termination for each heuristic according to

**Figure 4.** The relationship between the distances of the close node and the focal node with the costs and benefits for each solution for different networks. Figure (A) shows the relationship for a Watts-Strogatz network with  $N = 500$ , (B) a Barabási and Albert network with  $N = 500$ , (C) a Delaunay network with  $N = 500$ , and (D) a suburban school transportation network ( $N \approx 4000$ ). Each point represents a connection between a distant and close node, where the cost is the standardized length of the connection and the benefit is the number of new nodes within the distance to the focal node or school.

network size consistently followed the following pattern: ES>SA>HCVN>GA>HCS>HC. The genetic algorithm clearly outperformed the other heuristics, followed by simulated annealing, in terms of cost and benefit deviations (see Figure 5 (B), (D), and (F)).

## DISCUSSION, FUTURE WORK, AND LIMITATIONS

The local network connectivity problem introduced in this study is relevant to a wide range of applications and is nontrivial as the number of potential solutions can become large even for small systems. This class of combinatorial optimization problem highlights the difficulty in determining local search routines a priori. When the exhaustive search routine was applied to random networks and the real-world networks, the optimal solutions were found to be related to nodal characteristics, which entails a great complexity to find optimal solutions. Therefore, the heuristics employed to reduce the computational costs utilized nodal characteristics to search for solutions. Yet, these nodal characteristics were nonlinearly related to the solutions. Given the example networks, it should be noted that distance to the focal node was consistently related to the quality of the solution as this lowers connectivity length costs, while centrality was intermittently correlated with solution quality it provides greater benefit through more connections. Aside from the distance characteristic, these nodal characteristics also varied in their correlation (sign

and magnitude) with solution quality for different types of networks. This makes it difficult to exclude or prioritize specific nodal characteristics for local network connectivity optimization heuristics. This could arise from the four following issues: (a) the curse of dimensionality, i.e., large sparse subspaces in the solution space; (b) the nodal characteristics are highly correlated with each other; (c) outliers; and (d) the nodal characteristics are heterogeneous across the network. Results from the street networks in the transportation case-study found that the clustering coefficient was a poor measure due to the lack of triplets in the networks.

The optimization heuristics save computational time but vary considerably in their ability to find (near) optimal solutions. The stochastic hill climbing search was not effective due to the large neighborhood search space explored. In our experiment, the number of solutions checked at each iteration is  $> 300$  and resulted in a skewed probability distribution of objective values favoring the selection of low values. This degraded the efficiency of the method resulting in the selection of poor solutions. The variable neighborhood search method was similarly not reliable because of the significantly large neighborhood search space (the number of possible solutions explored at a given iteration could be  $> 5,000$ ), and had intermediate results with cost and benefit deviations. The simulated annealing heuristic consistently took longer to converge than the other optimization methods from the exploration of suboptimal solutions prior to moving towards better solutions, yet it was able to converge to values close to the optimal solution.

The computational costs and the variance in the importance of nodal characteristics for the random networks and real-world systems highlights the need for a heuristic that is able to quickly and effectively explore the solution space without getting stuck in a local optimum. The genetic algorithm provided in this work offers a solution to these issues and outperformed the other algorithms in terms of the consistently higher solution precision and accuracy. The genetic algorithm is able to dynamically reduce the size of the neighborhood search space and what variables to analyze. This reduction in the local solution search space allows the genetic algorithm presented here to converge on solutions near the optimal in a timely fashion. The heuristic is also able to compare solutions from distant search spaces with nonzero probability, thereby avoiding local optimums. The experiments indicate the power of biologically inspired algorithms to effectively explore multidimensional spaces (commonly found in natural systems) and their potential use in a wide variety of disciplines, including the specific applications for planning and crisis management presented above. The combinatorial optimization techniques employed here to identify and evaluate new street connections can also complement the optimization approaches used for other transportation planning problems, such as greenway planning (Linehan et al., 1995), bus stop locations (Ibeas et al., 2010; Delmelle et al., 2012), and health care accessibility (Gu et al., 2010).

There are several research directions from these proposed methods. Application of these methods and heuristics can be tested on multi-level networks, such as telecommunication systems, higher dimensional real-world networks (transportation networks with elevation), directed networks, and additional planar random networks (e.g., Gabriel graphs) and this should be conducted. Different distance measures to the focal node, such as the Hamming distance, could also be evaluated for different applications, and other real world examples should be used for analysis. The methods presented here simplified the costs and did not account for many real-world barriers that may restrict optimal new connections found through the heuristics. For example, the transportation case study did not include legal considerations, such as right-of-way, or physical barriers, such as highways or rivers. Furthermore, the methods presented here do not evaluate whether the new connections intersect existing edges, as in existing transportation networks, and attempts to incorporate such a feature resulted in unrealistic computational times.

## ACKNOWLEDGMENTS.

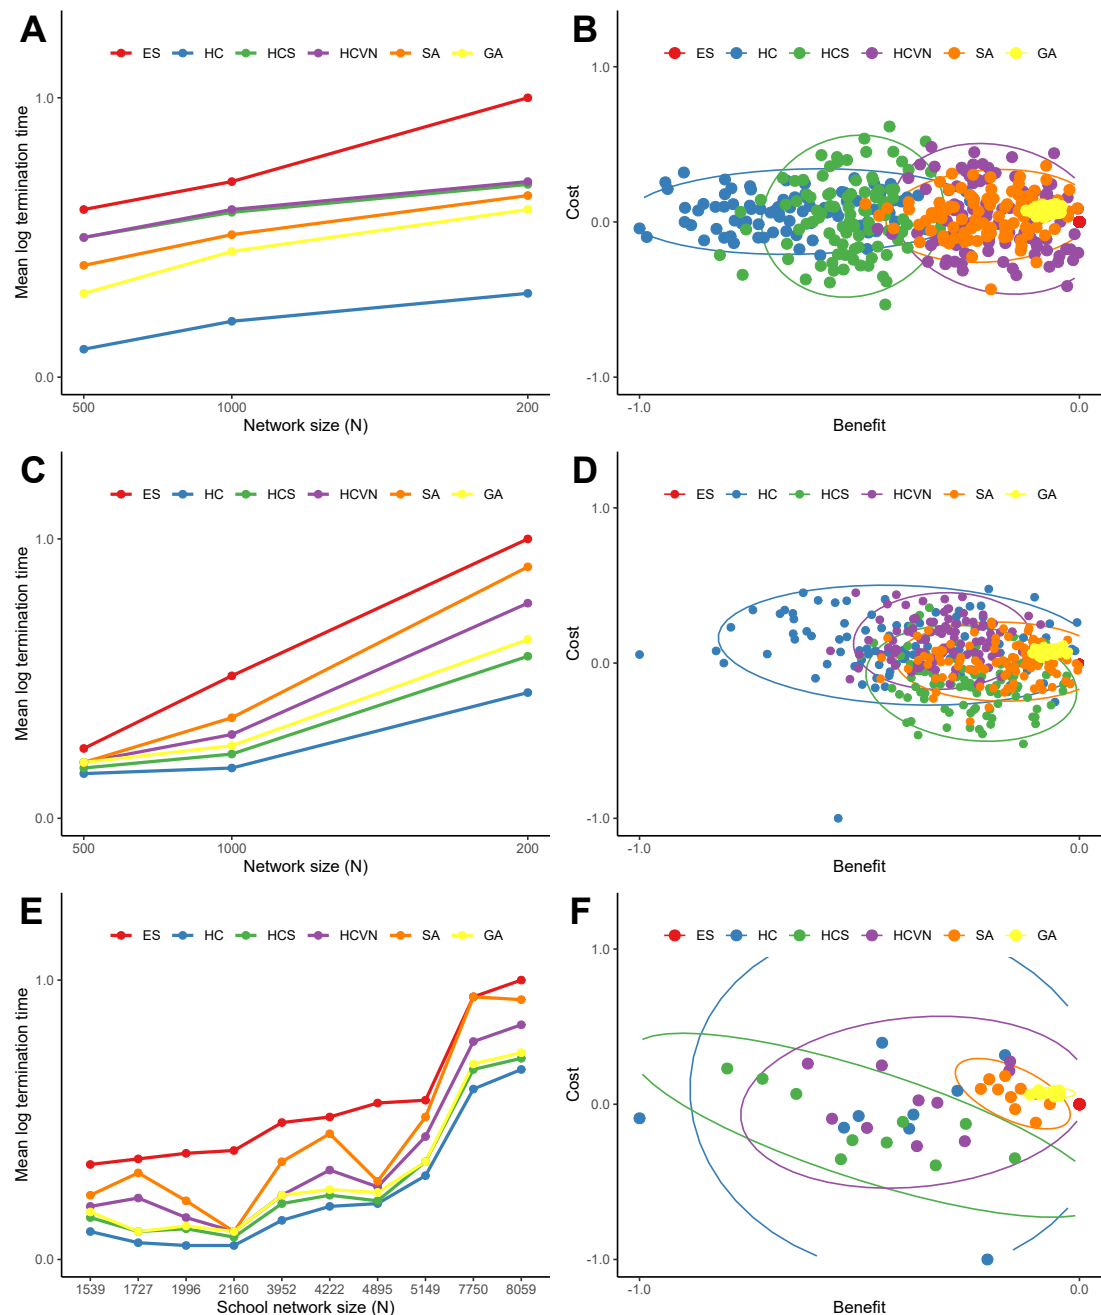

We would like to thank Alex Zendel (GIS Analyst at the Knoxville-Knox County Metropolitan Planning Commission) for providing the street networks and residential data around the schools.

**Figure 5.** The termination times (Figures A, C, and E) and the differences between the heuristic solution and the global optimal solution costs and benefits (Figures B, D, and F) for the heuristics applied to a sample of random networks and school networks: (A) and (B) Erdős-Rényi networks, (C) and (D) Delaunay networks, and (E) and (F) the ten school networks. For the random networks (Figures A and C) the termination times were averaged over 1000 networks for network sizes of 500, 1000, and 2000 nodes. The times were normalized by the exhaustive search time and log transformed. For the random network cost and benefit differences (Figures B and D) were drawn from a sample of 100 networks with 1000 nodes. The costs were the total lengths of the new connections and the benefits were the number of additional nodes for the solution. The costs and benefits were normalized with the global optimal solution from the exhaustive search, and a longer connection length is a positive cost difference whereas a shorter connection is a negative cost difference. For visualization, the 95-percent confidence ellipses drawn from the Hotelling's  $T^2$  statistic were included. The heuristic acronyms are the following: exhaustive search (ES), hill climbing (HS), stochastic hill climbing (HCS), hill climbing with variable neighborhood (HCVN), simulated annealing (SA), and genetic algorithm (GA).

Symbol	Definition
$v$	Network node
$e$	Network edge
$N$	Number of nodes in a given network, $N = \sum_i v_i$
$A$	Network adjacency matrix
$a_{ij}$	Adjacency matrix element $ij$
$F$	Focal node
$d(i, j)$	Network distance between nodes $i$ and $j$
$D$	Threshold distance from focal node
$N_C$	Set of close nodes, $N_C \subset N$
$N_D$	Set of distant nodes, $N_D \subset N$
$N_{i,j}^C$	Set of nodes that are now close after a new connection between nodes $i$ and $j$
$L_F$	Average path length to the focal node
$C(i, j)$	Cost of the new connection
$B(i, j)$	Benefit of the new connection
$\alpha$	Cost weight
$\beta$	Benefit weight
$t$	Optimization iteration
$O^t$	Optimal solution for iteration $t$
$O^*$	Optimal solution
$M$	Set of long-term memory solutions
$C_i^D$	Degree centrality of node $i$
$C_i^C$	Closeness centrality of node $i$
$\sigma_{ij}$	Shortest path between nodes $i$ and $j$
$\sigma_{jk}(i)$	Shortest path between nodes $j$ and $k$ that includes node $i$
$C_i^B$	Betweenness centrality of node $i$
$\lambda$	Eigenvalue
$x_i$	Eigenvector
$C_i^E$	Eigenvector centrality of node $i$
$\alpha_P$	Attenuation factor
$C_i^P$	Pagerank centrality of node $i$
$\eta$	Variable neighborhood size
$\mu$	Genetic algorithm mutation rate
$s$	Genetic algorithm selection coefficient
$P$	Population of solutions for the genetic algorithm
$f(i, j)$	Genetic algorithm fitness function
$\varepsilon_B$	Benefit error from heuristic
$\varepsilon_C$	Cost deviation from heuristic
$p$	Connection probability (Erdős-Rényi graphs and Klemm and Eguílez graphs)
$p_W$	Rewiring probability (Watts-Strogatz graphs)
$k_L$	Initial node degree (Watts-Strogatz graphs)
$m_0$	Initial network size (Barabási and Albert graphs and Klemm and Eguílez graphs)
$m$	Degree of new nodes (Barabási and Albert graphs)
$p_S$	node selection probability (Klemm and Eguílez graphs)
$p_R$	Edge removal probability (Delaunay and Voronoi random graphs)
$\bar{C}_D$	Mean degree of a network
$\bar{L}$	Average path length of a network
$c_i^w$	Weighted clustering coefficient for node $i$
$w_{ij}$	Weight of connection between nodes $i$ and $j$
$\bar{C}$	Weighted clustering coefficient of a network
$\bar{C}_r$	Weighted clustering coefficient of a completely random network
$\bar{L}_r$	Average path length of a completely random network
$\gamma$	Power law exponent
$P(n)$	Degree distribution
$E$	Efficiency of a network
$E_r$	Efficiency of a completely random network
$E_G$	Global efficiency of a network

**Table 1.** List of symbols and their definitions.

Local search selection criteria	
distance from focal node $d(i, F)$	degree centrality $C_i^D = \sum_j A(i, j)$
closeness centrality $C_i^C = 1 / \sum_j d(i, j)$	betweenness centrality $C_i^B = \sum_{j \neq i \neq k} \frac{\sigma_{jk}(i)}{\sigma_{jk}}$
eigenvector centrality $C_i^E = \frac{1}{\lambda} \sum_j A(i, j) x_j$	pagerank centrality $C_i^P = \alpha_P \sum_j A(i, j) \frac{x_j}{\sum_i A(i, j)} + \frac{1 - \alpha_P}{N}$
weighted clustering coefficient $c_i^w = \frac{1}{(C_i^D - 1) \sum_j a_{ij} w_{ij}} \sum_{j, h} \frac{(w_{ij} + w_{ih})}{2} a_{ij} a_{ih} a_{jh}$
