Science across all disciplines has become increasingly data-driven, leading to additional needs with respect to software for collecting, processing and analysing data. Thus, transparency about software used as part of the scientific process is crucial to understand provenance of individual research data and insights, is a prerequisite for reproducibility and can enable macro-analysis of the evolution of scientific methods over time. However, missing rigor in software citation practices renders the automated detection and disambiguation of software mentions a challenging problem. In this work, we provide a large-scale analysis of software usage and citation practices facilitated through an unprecedented knowledge graph of software mentions and affiliated metadata generated through supervised information extraction models trained on a unique gold standard corpus and applied to more than 3 million scientific articles. Our information extraction approach distinguishes different types of software and mentions, disambiguates mentions and outperforms the state-of-the-art significantly, leading to the most comprehensive corpus of 11.8 M software mentions that are described through a knowledge graph consisting of more than 300 M triples. Our analysis provides insights into the evolution of software usage and citation patterns across various fields, ranks of journals, and impact of publications. Whereas, to the best of our knowledge, this is the most comprehensive analysis of software use and citation at the time, all data and models are shared publicly to facilitate further research into scientific use and citation of software.

## 12 ABSTRACT

13 Science across all disciplines has become increasingly data-driven, leading to additional needs with  
14 respect to software for collecting, processing and analysing data. Thus, transparency about software  
15 used as part of the scientific process is crucial to understand provenance of individual research data and  
16 insights, is a prerequisite for reproducibility and can enable macro-analysis of the evolution of scientific  
17 methods over time. However, missing rigor in software citation practices renders the automated detection  
18 and disambiguation of software mentions a challenging problem. In this work, we provide a large-scale  
19 analysis of software usage and citation practices facilitated through an unprecedented knowledge graph  
20 of software mentions and affiliated metadata generated through supervised information extraction models  
21 trained on a unique gold standard corpus and applied to more than 3 million scientific articles. Our  
22 information extraction approach distinguishes different types of software and mentions, disambiguates  
23 mentions and outperforms the state-of-the-art significantly, leading to the most comprehensive corpus of  
24 11.8 M software mentions that are described through a knowledge graph consisting of more than 300 M  
25 triples. Our analysis provides insights into the evolution of software usage and citation patterns across  
26 various fields, ranks of journals, and impact of publications. Whereas, to the best of our knowledge, this  
27 is the most comprehensive analysis of software use and citation at the time, all data and models are  
28 shared publicly to facilitate further research into scientific use and citation of software.

## 29 1 INTRODUCTION

30 Science across all disciplines has become increasingly data-driven, leading to additional needs with  
31 respect to software for collecting, processing and analysing data. Hence, transparency about software  
32 used as part of the scientific process is crucial to ensure reproducibility and to understand provenance of  
33 individual research data and insights. Knowledge about the particular version or software development  
34 state is a prerequisite for reproducibility of scientific results as even minor changes to the software might  
35 impact them significantly.

36 Furthermore, from a macro-perspective, understanding software usage, varying citation habits and  
37 their evolution over time within and across distinct disciplines can shape the understanding of the evolution  
38 of scientific disciplines, the varying influence of software on scientific impact and the emerging needs for  
39 computational support within particular disciplines and fields. Initial efforts are made to provide publicly  
40 accessible datasets that link open access articles to respective software that is used and cited, for instance,  
41 the OpenAIRE Knowledge Graph (Manghi et al., 2019) or SoftwareKG (Schindler et al., 2020). Given  
42 the scale and heterogeneity of software citations, robust automated methods are required, able to detect  
43 and disambiguate mentions of software and related metadata.

44 Despite the existence of software citation principles (Smith et al., 2016; Katz et al., 2021), software  
45 mentions in scientific articles are usually informal and often incomplete—information about the developer

**Figure 1.** Annotated sentences from SOMESCI missing information required by software citation standards.

or the version are often missing entirely, see Fig. 1. Spelling variations and mistakes for software names, even common ones (Schindler et al., 2020), increase the complexity of automatic detection and disambiguation. Training and evaluation of information extraction approaches requires reliable ground truth data of sufficient size, raising the need for manually annotated gold standard corpora of software mentions.

Most works concerned with recognition of software mentions in scientific articles apply manual analysis on small corpora in order to answer specific questions (Howison and Bullard, 2016; Nangia and Katz, 2017) or are limited to specific software (Li et al., 2016, 2017). Automatic methods, enabling large scale analysis, have been implemented by iterative bootstrapping (Pan et al., 2015) as well as machine learning on manually engineered rules (Duck et al., 2016). However, both achieve only moderate performance. Extraction through deep learning with a Bi-LSTM-CRF (Schindler et al., 2020) shows promise, but requires sufficient and reliable ground truth data which only recently became available.

Available corpora (Duck et al., 2016; Schindler et al., 2020; Du et al., 2021) do not cover all available metadata features, cater for disambiguation for different spelling variations of the same software or distinguish between the purpose of the mention such as creation or usage. In SOMESCI (Schindler et al., 2021b), we have introduced a gold standard knowledge graph of software mentions in scientific articles. To the best of our knowledge, SOMESCI is the most comprehensive gold standard corpus of software mentions in scientific articles, created by manually annotating 3756 software mentions with additional information about types of software, mentions and related features, resulting in 7237 labelled entities in 47,524 sentences from 1367 Pubmed Central (PMC) articles.

In this work, we provide a large-scale analysis of software usage and citation practices facilitated through an unprecedented knowledge graph of software mentions and affiliated metadata generated through a supervised information extraction model trained on SOMESCI and applied to more than 3 million scientific articles. In summary, our contributions include:

- **A large-scale analysis of software usage** across 3,215,386 scholarly publications covering a range of diverse fields and providing unprecedented insights into the evolution of software usage and citation patterns across various domains, distinguishing between different types of software, mentions as well as rank of journals and impact of publications. Results indicate strongly discipline-specific usage of software and an overall increase in software adoption. To the best of our knowledge, this is the most comprehensive analysis of software use and citation at the time.
- **A comprehensive knowledge graph of software citations** in scholarly publications comprising of 301,825,757 triples describing 11.8 M software mentions together with types and additional metadata. The knowledge graph is represented using established vocabularies capturing the relations between citation contexts, disambiguated software mentions and related metadata and provides a unique resource for further research into software use and citation pattern.
- **Robust supervised information extraction models for disambiguating software mentions and related knowledge** in scholarly publications. As part of our experimental evaluation, our model based on SciBERT and trained on SOMESCI (Schindler et al., 2021b) for Named Entity Recognition (NER) and classification outperforms state-of-the-art methods for software extraction by 5 percentage points (pp) on average. Software mentions are disambiguated and different variations interlinked, e.g., abbreviations and name- and spelling-alternatives, of the same software.

Through these contributions, we advance the understanding of software use and citation practices across various fields and provide a significant foundation for further large-scale analysis through an unprecedented dataset as well as robust information extraction models.

The remaining paper is organised as follows. Related work is discussed in the following section, whereas the Section *Methods and Materials* introduces developed information extraction methods together with datasets used for training and testing. Section *Results: Information Extraction Performance* describes the performance results obtained on the various information extraction tasks, while the Section *Results: Analysis of Software Mentions* introduces an in-depth analysis of the extracted data. Key findings are discussed in the *Discussion*, followed by a brief conclusion and introduction of future work.

## RELATED WORK

### Requirements for large scale software citation analyses

Software usage based mentions in scientific articles have been analysed for several reasons including mapping the landscape of available scientific software, analyses of software citation practices and measuring the impact of software in science in general (Krüger and Schindler, 2020). This includes manual analyses based on high quality data, such as Howison and Bullard (2016); Du et al. (2021); Nangia and Katz (2017); Schindler et al. (2021b) but also automatic analyses such as Pan et al. (2015); Duck et al. (2016); Schindler et al. (2020). While manual analyses provide highly reliable data, results often only provide a small excerpt and do not generalize due to small sample size. Analyses based on automatic data processing, in contrast, allow to make more general statements, for instance, regarding trends over time or across disciplines, but require high quality information extraction methods which themselves rely on reliable ground truth labels for supervised training. Table 1 compares manual and automatic approaches with respect to sample size and quality indicators such as Inter-Rater Reliability (IRR) or FScore. Manual approaches provide substantial to almost perfect IRR, but are restricted to less than 5,000 articles at most. Howison and Bullard (2016), for instance, analyzed software mentions in science by content analysis in 90 articles. The main objective of Du et al. (2021) and Schindler et al. (2021b) was to create annotated corpora of high quality for supervised learning of software mentions in scientific articles. While Du et al. (2021) provide labels for software, version, developer, and URL for articles from PMC, which is multidisciplinary but strongly skewed towards Medicine (see Table A11) and Economics, Schindler et al. (2021b) exclusively used articles from PMC, and provide labels for software, a broad range of associated information, software type, mention type, and for disambiguation of software names.

Early automatic approaches, such as Pan et al. (2015) and Duck et al. (2016) achieve only moderate recognition performance of .58 and .67 FScore, but perform analyses on up to 714 K articles raising doubts about the reliability and generalizability of the described results. Pan et al. (2015) used iterative bootstrapping—a rule-based method that learns context rules—as well as a dictionary of software names based on an initial set of seed names. Duck et al. (2016) employ machine learning classifiers on top of manually engineered rules. With the availability of large language models and deep learning methods for sequence labelling, Schindler et al. (2020) employed a Bi-LSTM-CRF and achieved an FScore of .82 for the recognition of software mentions in scientific articles. Most recently, Lopez et al. (2021) compare Bi-LSTM-CRF and SciBERT-CRF models on Softcite (Du et al., 2021) software entity recognition at paragraph level. They achieve .66 and .71 FScore, respectively, and further improved performance to .74 FScore by linking entities to Wikidata during postprocessing.

Beside high recognition rates, and thus the basis for reliable statements, Schindler et al. (2020) demonstrate the capabilities of semantic web technologies for information structuring and data integration with respect to analyzing software usage. They provide a Knowledge Graph (KG)—SoftwareKG—representing a data source for structured data access for analysis. The disambiguation of software mentions allows to draw conclusion on the level of software rather than software mentions, even with spelling variations. Finally, the linked nature of KGs allows the integration of external data sources enabling further analyses. Following the direction of Schindler et al. (2020), large scale analyses of software mentions in scholarly articles requires (1) robust information extraction and disambiguation techniques that achieve results on the level of manual approaches, and (2) the provision of all data in a standardised way that allows the reuse and the integration of external knowledge.

### Previous analyses of Software in Scholarly Publication

As described above, previous studies on software mentions in scholarly publication were based on high quality manual analyses with small sample sizes or automatic analyses with large sample size but moderate quality. Most studies report basic descriptive statistics such as the number of overall mentions given in Table 1 or the distribution of software mentions over different software. Howison and Bullard (2016) report an average of 3.2 software mentions per article in Biology while Duck et al. (2016) report 12.9. In PMC, Duck et al. (2016) report an average of 5.5 mentions while Du et al. (2021) report 1.4 and Schindler et al. (2021b) 2.6. Similarly, Pan et al. (2015) and Schindler et al. (2020) report values of 2.7 and 2.6 for sub-selections of PLoS. Interestingly, Du et al. (2021) report a low value of 0.2 for Economics and Duck et al. (2016) a high value of 30.8 for Bioinformatics. Some of those results clearly show disciplinary differences, while others such as the PMC discrepancies might be attributed to methodical differences, including publication time of articles in the investigated sets, for instance, articles within Du et al. (2021) are significantly older than for Schindler et al. (2021b) which could result in a lower average software usage. This is also supported by the finding of Duck et al. (2016) who analyse software mentions up to 2013 and report a rapid increase in software usage between 2000 and 2006.

Other findings regard the distribution with respect to unique software names. Pan et al. (2015) report that 20% of software names account for 80% of mentions. Duck et al. (2016) report that 5% of software names account for 47% of mentions, and, similarly, 6.6% of entities are responsible for 50% of mentions in Schindler et al. (2021b). Therefore, all prior studies agree that the distribution of software within articles is highly skewed, pointing towards the fact that there are few pieces of general purpose software such as SPSS or R that support the scientific infrastructure. On the other hand, there is a high number of rarely mentioned software that is likely to be highly specialized towards problems and domains. Duck et al. (2016) perform an analysis of domain specific software to investigate disciplinary differences in software usage. They were able to confirm the existence of domain specific software and showed, for instance, that 65% of software used in medicine was not used in other analyzed domains. They also focus on journal specific software and applied a clustering analysis with respect to journal and software name.

Completeness of software mentions and citation is of high importance since employed software can only be clearly identified with sufficient information. Including aspects such as the specific version or developer of software is, therefore, essential for provenance of study results or to provide credit for the creation of scientific software. For this purpose, guidelines for proper software citation have been established (Smith et al., 2016; Katz et al., 2021) that recommend the following information to be included: name, author, version/release/date, location, venue, and unique ID, e.g., DOI. Howison and Bullard (2016) analyze the completeness of software mentions with respect to the following information: formal citation 44%, version 28%, developer 18% and URL 5%. Based on the given information they were able to locate 86% of software online, but only 5% with the specific version. Completeness analyses by Du et al. (2021) showed that a total of only 44% of software mentions include further information with version being included in 27%, publisher in 31%, and URL in 17%. An analysis by Schindler et al. (2021b) showed that 39% mentions included a version, 23% a developer, 4% a URL and 16% a formal citation. Overall, this shows that software mentions are still often informal and incomplete. Further, there are also some notable differences between the percentages found within different studies. The problem of formal and informal software citation was also included in the automatic analysis of Pan et al. (2015) who identified formal citations for recognized software by automatic string pattern matching. They report a correlation between the number of mentions of a software with its formal citation frequency.

Availability of used software is crucial as studies conducted with commercial software might not be

reproducible by other research teams. Furthermore, implementation details for non open source software cannot be reviewed by the scientific community and can potentially bias study results. Therefore, different studies included analyses regarding commercial, free and open source software usage. Pan et al. (2015) found that of the most frequent software mentions, which were labelled for availability manually, 64% are free for academic use. Moreover, they found that free software received more formal citations than commercial software. Howison and Bullard (2016) include an analysis for accessibility, license and source code availability and report that commercial software is more likely to be mentioned similar to scientific instruments (including details on developer and its location) while open access software is more often attributed with formal citation. However, they also note that there is no overall preferred style for any group of software. Schindler et al. (2020) show a comparison of software mention numbers for free, open source and commercial software over time that showed no clear trend towards a specific group.

Beside analyses about software in scholarly publications in general, several studies focus on particular aspects such as specific software or the relation of software usage to bibliometric measures. Li et al. (2016), for instance, analyze mentions of the specific engineering software (LAMMPS) and found that the given information is often not complete enough to determine how it was applied with respect to version, but also regarding software specific settings. Li et al. (2017) analyze software citation for R and R packages. They report inconsistency resulting from a variety in citation standards, which are also not followed well by authors. Overall, they show a trend towards more package mentions, and find a comparably high number of formal citations for R packages (72%). Mayernik et al. (2017) discuss data and software citation and conclude that there is no impact measure for software available. Allen et al. (2018) analyse the availability of source code in astrophysics and report that it could only be located for 58% of all mentions. Pan et al. (2018) analyze the completeness for usage statements of three specific bibliometric mapping tools and find provided mentions in 30% of cases, URLs in 24%, and formal citations in 76%. They argue that the high formal citation might be due to good author citation instruction given by the tools. Howison and Bullard (2016) report that articles published in high impact journals have mentioned more software. The platform swMATH (Greuel and Sperber, 2014) aims to establish a mapping of software used in mathematical literature by manually labelling software present in zbMATH articles pre-filtered through an automatic, heuristic search.

Most studies agree that software citation is important but often incomplete and report similar trends about the frequency of software mentions. They deviate, however, when it comes to particular numbers such as software mentions per article. This could be the result of (1) discipline specific citation habits, (2) small sample sizes in analysis studies, and (3) insufficient quality of automatic information extraction. A large scale study based on reliable automatic information extraction is required to draw conclusions across different disciplines.

## METHODS AND MATERIALS

### Information Extraction

#### Training Dataset

We apply automatic information extraction based on supervised machine learning for recognizing software in science and use SOMESCI—Software Mentions in Science—a corpus of annotated software mentions in scientific articles (Schindler et al., 2021b). Additionally to 3756 software annotations in 1367 PubMed Central (PMC) articles, it contains annotations for different software types such as *Programming Environment* or *Plug-In*, mention types such as *Usage* or *Creation*, and additional information such as *Version* or *Developer*. Moreover, it provides unique entity identities for all software annotations, which allows to not only develop a system for software name recognition but also for disambiguating names, an essential inference step in building a software Knowledge Graph. This level of detail is not represented in other available software datasets such as BioNerDs (Duck et al., 2016) or Softcite (Du et al., 2021). SOMESCI does also contain recent articles and is, therefore, suited to represent the recent shift in awareness and recommendations for software citation. Quality of SOMESCI annotations was assessed through IRR and is reported to be high with a value of  $\kappa=0.82$ . SOMESCI is available from Zenodo<sup>1</sup> and an annotated example with markup from the web-based annotation tool BRAT (Stenetorp et al., 2012) is given in Fig. 2. For all reported information extraction problems described below we use the same 60:20:20 division in train, development, and test set as the SOMESCI baseline.

<sup>1</sup><https://doi.org/10.5281/zenodo.4968738>

The protein-protein interaction networks were further separated into different clusters and biological significance of these clusters were

**Figure 2.** Sentence from SOMESCI annotated with respect to software, additional information, mention type, and software type as well as corresponding relations.

SOMESCI Statistics

# Sentences w/ Software	2,728
# Sentences w/o Software	44,796
# Annotations	7,237
# Software	3,756
# unique Software	883
# Relations	3,776
Software Type	<i>Application, PlugIn, Operating System (OS), Programming Environment (PE)</i>
Mention Type	<i>Allusion, Usage, Creation, Deposition</i>
Additional Information	<i>Developer, Version, URL, Citation, Extension, Release, License, Abbreviation, Alternative Name</i>

**Table 2.** Overview of the SOMESCI corpus. Further details can be found in Schindler et al. (2021b).

An overview of the different annotations along with the overall statistics of the SOMESCI dataset is given in Table 2. SOMESCI distinguishes each mention of a software by two types: mention and software. Mention type can take the values of *Usage* if the software was actively used and is contributing to the articles results, *Creation* if it was created in the scope of the article, *Deposition* if it was created and additionally published, and *Allusion* if its name was merely stated, e.g., in an comparison with another software. Similarly, software type is distinguished between, *Application* if the software can be run as a stand-alone software, *PlugIn* if it is an extension to an existing host software, *Operating System* and *Programming Environment* if it is a framework for writing and executing program code. More details on the different types and relations are provided in the Section Taxonomy for Software and Related Information.

### Inference Dataset

The inference dataset includes 3,215,386 articles indexed in PMC acquired via bulk download<sup>2</sup> on January 22, 2021. Construction of SoftwareKG requires metadata and plain text of each article. To acquire the information, Journal Article Tag Suite (JATS) was used instead of the also available Portable Document Format (PDF). PDF is the standard form in which humans consume scientific articles, however, there are drawbacks for machines due to formatting artifacts caused by elements such as headers, footers, page numbering, or multi-column formats. While some tools, such as GROBID (GROBID, 2021), perform well on pdf to text conversion, using JATS prevents errors resulting from text formatting. JATS on the other hand is an XML-based format, and while specific tagging conventions vary between different journals indexed in PMC, they all follow a common scheme, making it a suited source for both metadata and plain text. Both were extracted using a custom implementation available in the associated source code<sup>3</sup>.

### Entity Recognition and Classification

The objective of this information extraction step is to recognize software mentions and associated additional information, and to classify software according to its *Software Type* and *Mention Type*. The target labels are summarized in Table 2. The task is modelled as NER sequence tagging problem where each sentence is considered as a sequence of tokens each of which has to be assigned a correct output tag.

<sup>2</sup><https://www.ncbi.nlm.nih.gov/pmc/tools/ftp/>

<sup>3</sup><https://github.com/dave-s477/SoftwareKG>

Parameter	default
Learning Rate (LR)	1e−5
Sampling	all data
Dropout	0.1
Gradient Clipping	1.0

**Table 3.** Hyper-parameters considered for BERT models including their default setting.

260 Different suited state-of-the-art machine learning models are considered for the task. We compare the  
261 given baseline results on SOMESCI (Schindler et al., 2021b), which were established by an un-optimized  
262 Bi-LSTM-CRF model, to other machine learning models suited for scientific literature, for instance,  
263 SciBERT (Beltagy et al., 2019). To establish a consistent naming scheme we label all implemented and  
264 tested models by *type*, classification *target* and *optimization* state:  $M_{type,target,optimization}$ . Results for NER  
265 are reported by mean and standard deviation for repeated training runs because performance can vary  
266 between runs due to randomization in initialization and training. Results of at least 4 different training  
267 runs are provided for hyper-parameter optimization and 16 for final performance estimation. The best  
268 model is chosen only based on the problem of identifying software mentions ( $M_{-,sw,-}$ ) as we consider it  
269 the most important quality measure and the main problem all other tasks relate to.

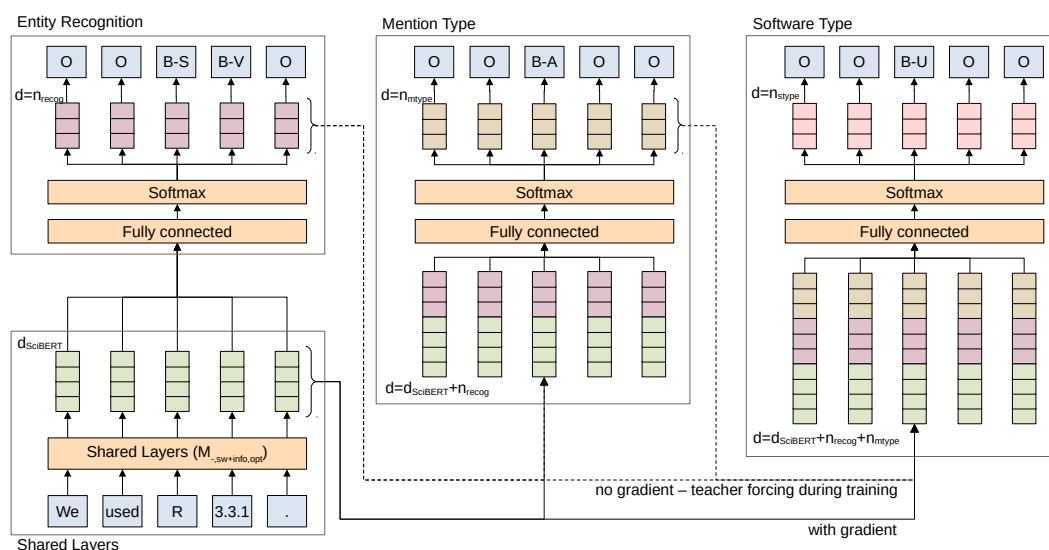

270 Bi-LSTM-CRFs ( $M_{L,sw,-}$ ) were selected as they are well established for NER and have been reported  
271 to achieve state-of-the-art results (Ma and Hovy, 2016). Further, they have previously been applied to the  
272 problem of recognizing software in scientific literature (Schindler et al., 2020, 2021b; Lopez et al., 2021).  
273 More details on the model can be found in (Ma and Hovy, 2016; Schindler et al., 2020) as well as in the  
274 implementation details in our published code.

275 BERT (Devlin et al., 2019) is a transformer-based model that is pre-trained on a masked language  
276 prediction task and has proven to achieve state-of-the-art performance across a wide range of NLP  
277 problems after fine-tuning. Different adaptations of the BERT pre-training procedure exist for scientific  
278 literature resulting in the two well established models BioBERT (Lee et al., 2019) ( $M_{BB,sw,-}$ ) and  
279 SciBERT (Beltagy et al., 2019) ( $M_{SB,sw,-}$ ). While BioBERT is pre-trained on Pubmed abstracts as well as  
280 PMC full-texts SciBERT is pre-trained on full-text articles from semantic scholar with 18% of articles  
281 coming from the domain of Computer Science and the remaining 82% from Biomedicine. To reduce run-  
282 time requirements, hyper-parameter optimization was only performed for the best performing BERT model  
283 that was chosen by comparing both models after fine-tuning with the default configuration summarized in  
284 Table 3. The parameter *Sampling* reduces the size of the training set by randomly suppressing sentences  
285 from the training corpus that do not contain software.

286 The overall, best model based on the development set is selected and extended to solve the 3 main  
287 objectives ( $M_{-,sw+info,-}$ ) of the initial information extraction step: (1) recognize software mentions  
288 and corresponding additional information, (2) classify software type of extracted software mentions,  
289 (3) classify mention type of software mentions. The combined problem is modelled as hierarchical  
290 multi-task sequence labelling and illustrated in Fig. 3. Approaching all tasks in one model has the benefit  
291 that multi-task learning can improve recognition performance and help to learn better representations  
292 if the given tasks are related as it implicitly increases the sample size (Ruder, 2017). Therefore, the  
293 main layers of the model share their weights across all sub-tasks and they are updated with loss signals  
294 from all individual tasks. The output of each sub-task is calculated by a separate fully connected layer  
295 with softmax activation. For backpropagation we chose the simple approach of summing over the three  
296 cross-entropy losses, however, this could be further explored in the future, for instance, as described by  
297 Kendall et al. (2018).

298 The hierarchical component is added by passing the classification result of lower hierarchy sub-tasks  
299 as input to higher sub-tasks. The classification layer for mention type receives the output of software  
300 recognition and the software type layer the output of both software recognition and mention type. There  
301 is no gradient passed backward through the hierarchy so the weight updates in each classification layer  
302 are only based on the individual task loss, but additional information is available to enhance classification  
303 performance. Teacher forcing—passing the correct prediction regardless of the actual prediction—is  
304 performed during training with respect to the output of lower layers in the hierarchy. As a result, we  
305 expect better update steps and faster learning convergence by providing more gold label information to

**Figure 3.** Illustration of the employed multi-task, hierarchical, sequence labelling model. Features are generated based on shared layers. The features are passed to 3 separate tasks and loss signals are used to update shared weights by simple summing. Outputs of classification layers are passed back to the network as input features to other classification layers, depicted from left to right in the image. Teacher forcing is used during training to replace potentially wrong classification outputs being passed in the network with gold label data. Colors represent similar types of information.

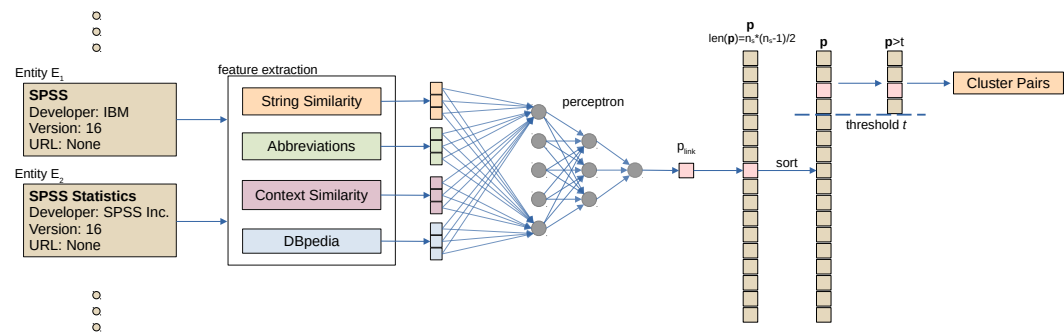

Sentence	We	used	SPSS	Statistics	16	.
Entities	O	O	B-App	I-App	<u>I-Ver</u>	O
Types	O	O	B-Use	I-Mention	O	O
Fixed	O	O	B-App-Use	B-App-Use	B-Ver	O

**Table 4.** Example for enforcing tagging consistency. Inconsistencies are underlined.

later classification layers. Additionally, teacher forcing should motivate the constraint that a software type or mention type should only be classified if a software was classified before. Note, that hyper-parameters for the  $M_{-sw+info,opt}$  are based on the best set of parameters identified for software recognition  $M_{-sw,opt}$ .

As labels for multiple tasks had to be combined with potential tagging inconsistencies for each task we experimented with adding a CRF layer on top of BERT to improve performance by learning inter-dependencies and constraints between labels. However, we found no improvement in performance but additional time complexity and did not further pursue the model. Instead we enforce tagging consistencies by applying a simple set of rules: (1) all I-tags without leading B-tags are transformed to B-tags—including I-tags that do not match their leading B-tags; (2) entity boundaries for higher hierarchy tasks are adjusted to the base task entity boundaries; (3) when there are multiple conflicting labels in higher hierarchy steps for one identified software entity, the label for the first token is chosen. An example is given in Table 4.

The performance of  $M_{-sw+info,opt}$  is evaluated against the SOMESCI baseline (Schindler et al., 2021b) described above. In contrast to our implementation, information is not shared between tasks in the baseline model and instead all classifications are performed hierarchically and individually. Therefore, the reported results for the baseline are subject to error propagation as recognition of additional information, software type classification and mention type classification all assume an underlying perfect software recognition. As our implementation does take error propagation into account the SOMESCI baseline overestimates performance in a direct comparison.

**Figure 4.** Overview of the software name disambiguation. For all pairs of extracted software entities ( $E_1, E_2$ ), features are extracted (feature extraction) and used to determine a probability of linking (perceptron). Finally, agglomerative clustering is performed to cluster similar software names.

### Relation Extraction

For Relation Extraction (RE), the task of classifying if and which relationships exist between entities, we considered all relations available from the training dataset. All additional information can be related to software, versions and developers to licenses, and URLs to licenses or developers. Software mentions can be related to each other by the *plugin-of* relation, representing one mention as the host software and the other as the PlugIn, or by the *specification-of* relation if both mentions refer to the same real world entity. Some possible relations are also depicted in Fig. 2. Its important to note that RE is the second information extraction step and, therefore, directly dependent on entity extraction. For developing and testing RE we rely on gold level entities, but in practice RE performance is expected to be lower due to false negatives and false positives resulting from entity extraction errors.

SOMESCI (Schindler et al., 2021b) provides a baseline model for classifying relations between software associated entities based on manually engineered features and an optimized Random Forest classifier. The features take into account (1) entity order, (2) entity types, (3) entity length, (4) entity distance, (5) number of software entities, (6) sub-string relations, and (7) automatically generated acronyms, all implemented to yield Integer or Boolean results.

We chose to adapt and enhance the SOMESCI baseline model instead of using more complex deep learning models because the baseline achieved good results on the task. Moreover, RE for software associated entities is less challenging as general RE problems as we impose a large number of constraints on how entities can be related. To improve the given rule set we individually fine-tuned the implementation of each rule. Moreover, we experimented with multi-layer perceptrons and SVMs as alternative to the Random Forest classifier. In initial tests, they did not achieve better performance and we chose to retain the Random Forest classifier as it has the benefit of offering better explainability. The Random Forest was trained with 100 trees, unlimited maximum depth, and no restrictions to splitting samples.

### Software Disambiguation

Software is referred to by different names due to abbreviations, geographical differences, or time. Schindler et al. (2020), for instance, report up to 179 different spelling variations for the commonly used software SPSS. This raises the need for software name disambiguation as a core requirement for constructing SoftwareKG. SOMESCI provides a gold standard for this problem through manually assigned unique identifiers in form of links to external knowledge bases. However, existing knowledge bases, such as Wikidata (Vrandečić, 2012) or DBpedia (Auer et al., 2007), are sparse when it comes to scientific software which is illustrated by an analysis of the SOMESCI disambiguation ground truth: only 205 of 883 (23%) unique and 2228 of 3717 (60%) software mentions are represented in Wikidata. Therefore, we adapt and develop an entity disambiguation method able to handle previously unknown software names such as those from creation statements without the need to link to external knowledge bases, and, in consequence, contribute to establish a more complete KG of software.

The objective of software entity disambiguation is as follows: Given a pair ( $E_1, E_2$ ) of software entities the goal is to determine whether they refer to the same real world entity. For that purpose we

employ hierarchical clustering following the procedure illustrated in Fig. 4. First, for each pair manually engineered features are calculated, resulting in a feature vector  $\mathbf{v}_{E_1, E_2}$ . Features take into account: (1) string similarity, (2) similarity of extracted context information, (3) automatically generated abbreviations, and (4) software related information queried from DBpedia.

For each pair  $(E_1, E_2)$ , vector  $\mathbf{v}_{E_1, E_2}$  is mapped to a probability estimate  $p_{link}$  for if they should be linked by a 4-layer perceptron ( $15 \times 10 \times 5 \times 1$ ) with low complexity  $p_{link} = f_{perceptron}(\mathbf{v}_{E_1, E_2})$ . The model is trained supervised to predict if a link exist  $l = \{0, 1\}$  based on splitting all possible combinations from the ground truth set in train, development and test set in a 60:20:20 ratio. Since the class was trained as a binary classification the output of the perceptron is the result of a sigmoid layer  $d \in [0, 1]$  and is used in combination with a threshold in the following steps. We considered applying dropouts but found a decreasing performance in initial tests. We also did not find any increase in performance for increasing model complexity.

For disambiguation we have to consider the influence of the sample size on the density of samples in the resulting features space. For  $n$  extracted mentions of software the number of entity pairs that need to be disambiguated accumulates to  $n^2 - n$ . In the small training set data points are overall less dense while the large inference set will likely contain a large number of close samples. Moreover, the inference set will contain false positive mentions with strong resemblance to software resulting from expected prediction errors in the entity extraction step. This makes it difficult to find reliable decision boundaries on the training set alone. During testing it became apparent that due to the described effect the perceptron trained only on gold standard labels could not learn suited decision boundaries to disambiguate entities pairs in the inference set. To counteract this problem, data augmentation was applied to add further entities resembling false positive extracted software names, which should not be linked to any other mentions. To simulate closeness to existing software names the new samples were generated by recombining sub-strings of existing samples, for instance, *ImageJ* and *SPSS Statistics* could be combined to form *Image Statistics*. During creation we made sure to not re-create given software names as well as duplicates. In total,  $2n$  augmented samples were created once for the  $n$  original samples and included at each training epoch. They were also included in the test set with the same factor in order to estimate performance under the chance of false positive samples. As we only add negative samples to the test set there is no risk to overestimate the performance with the employed metrics of precision and recall.

Based on the predicted probabilities  $p_{link}$  for entity pairs a agglomerative clustering is performed. In each step, the two clusters with the largest probability are combined. As stopping criterion the threshold  $t$  is introduced and defined as the minimal probability for which pairs are linked. It is optimized based on the available gold standard labels. At this point the creation of reliable decision boundaries within the densely populated feature space is also an issue. To counteract it the threshold is optimized taking into account all available data points from gold standard and inference set by combining both sets. This approach allows to evaluate how well the gold labelled mentions are clustered within the densely populated feature space. The performance of the hierarchical clustering is then estimated based on how well the gold label mentions are clustered at the best achieved FScore for the selected threshold  $t$ .

To combine probabilities between clusters during hierarchical clustering, we considered single and average linkage and found almost identical performance for varying thresholds based on gold standard mentions only. Given the similar performance during the initial tests, single linkage was preferred as it offers benefits in run-time and space complexity because it allows to re-use the initially calculated similarities. Average linking, in contrast, would require additional computation for the per-cluster-pair average similarity. Due to the run-time issues described below an evaluation of average linkage would not have been feasible with the evaluation method described above. Single linkage was then applied and evaluated as described.

A major issue we faced for disambiguation was run-time complexity as the number of pairs accumulates to  $n^2 - n$  with  $n_s > 11M$  software mentions. Therefore, we had to optimize for run-time complexity. Our initial optimization step was to assume feature vectors between entities  $E_1$  and  $E_2$  to be symmetric  $\mathbf{v}_{E_1, E_2} = \mathbf{v}_{E_2, E_1}$  reducing the number of required compares to  $\frac{n(n-1)}{2}$ , even so they are not strictly symmetric because string length of entities are included as normalization factors. Further, we made the assumption that all software with the same exact string refers to the same real-world software entity and only included a limited number of  $n_{unique} = 6$  samples of each name. The work of Schindler et al. (2021b) showed that this can in rare cases lead to false positive clustering, but in this case the benefit outweighs this risk because otherwise the computation would not have been feasible. Disambiguation on the remaining set of

~1.4 M mentions took approximately 6 days, with feature calculations parallelized over 6 Intel® Xeon® Gold 6248 CPU (2.50GHz, 40 Threads).

Schindler et al. (2021b) provide a baseline implementation for entity disambiguation on SOMESCI which uses manually engineered rules and external knowledge from DBpedia to disambiguate software names. For completeness we compare to baseline results, however, as explained above, the density of the features space increases strongly by including additional data samples and our evaluation specifically includes augmented negative samples. Thus, the implemented method cannot directly be compared to the baseline in terms of disambiguation quality, but serves as an indicator.

## SoftwareKG: Knowledge Graph of Software Mentions

### Taxonomy for Software and Related Information

We define software and its related information following the taxonomy presented by Schindler et al. (2021b) that describes the intricacies of in-text software mentions in scientific publications. The taxonomy distinguishes *Type of Software* describing which artifacts are considered as software, *Type of Mention* describing the context in which software was applied, and *Additional Information* that is provided to closer describe a software entity.

**Type of Software** Based on the distinction between end-user application (*software*) and *package* introduced by Li et al. (2017), Schindler et al. (2021b) distinguish the following categories of software:

*Applications* are standalone programs, designed for end-users, that usually result in associated data or project files, e.g., Excel sheets. This definition includes software applications that are only hosted and available through web-based services, but excludes web-based collections of data. The definition also excludes databases that are used to store collections of scientific data. To be considered as an *application* a web-service has to provide functionality beyond filtered access to data.

*Programming Environments (PE)* are environments for implementing and executing computer programs or scripts. They are built around programming languages such as Python but also integrate compilers or interpreters in order to create executables from developed code. PEs play an important role in many scientific investigations and are particularly important for computationally heavy scientific disciplines such as computer science.

*Plugins* are extensions specifically developed to be used with existing applications or PEs and cannot be used individually. As such, in the context of PEs, the category *PlugIn* could also be called package or library. Often, the original application can be concluded from the PlugIn, e.g., scikit-learn is a frequently used Python package for machine learning. The usage of Plugins is well established in the scientific community as it allows to extend the function range of well established software libraries. This allows to implement custom software without the need to establish more complex stand-alone application.

*Operating Systems (OS)* build the basis for running software on a computer by managing its hardware components and the execution of all other software. OS are necessary when running a software application and they are, overall, less mentioned than other software. In many cases authors still choose to attribute common operating systems such as Windows, OS X, or Android as well as lesser used ones such as Ubuntu or Raspbian.

**Type of Mention** The definition of Schindler et al. (2021b) introduces a hierarchy of reasons why software is mentioned within scholarly articles and is based on the basic distinction between *mention* and *usage* introduced by Howison and Bullard (2016):

*Allusion* of software describes each mention of a software name within a scholarly article. Aside appearance of the software name there are no further requirement for an allusion. It should especially be noted that no indication of actual usage is required, for instance, a fact about the software can be stated or multiple software can be compared. In the context of software mentions, allusions are comparable with scholarly citations used to refer to related work.

465 *Usage* (sub-type of Allusion) defines that a software made a contribution to the study and was actively  
 466 used during the investigation, which makes the software a part of the research's provenance.  
 467 Therefore, usage statements are required to allow conclusions regarding provenance. This is in line  
 468 with the definition of software usage by Lopez et al. (2021).

469 *Creation* (sub-type of Allusion) indicates that software was developed and implemented as part of a  
 470 scientific investigation and is itself a research contribution. Knowledge of creation statements  
 471 allows to track research software to its developers in order to provide credit to them as well as to  
 472 discover and map newly published scientific software.

473 *Deposition* (sub-type of Creation) indicates that a software was published in the scope of a scientific  
 474 investigation on top of being developed. Creation and deposition statements can be distinguished  
 475 based on the additional information provided by the authors such as a URL or the corresponding  
 476 publication license. Deposition statements, therefore, allow to provide additional information about  
 477 discovered scientific software.

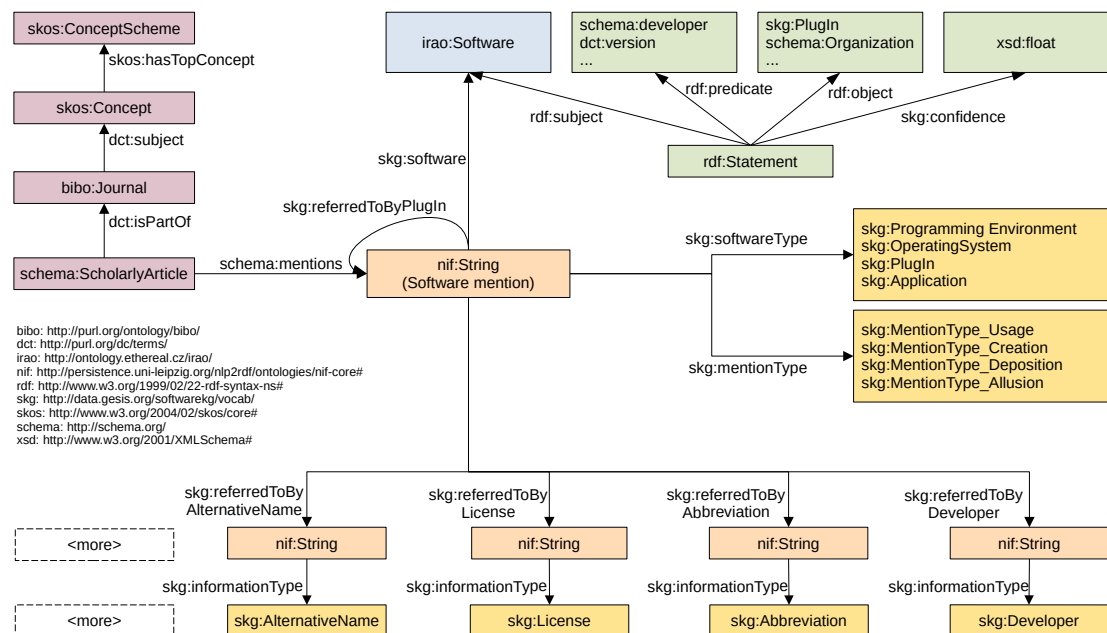

478 Both *Type of Software* and *Type of Mention* are required to fully describe a software mention in a scientific  
 479 publication.

480 **Additional Information** Software is constantly updated and changing. Moreover, software names are  
 481 ambiguous (Schindler et al., 2020). Therefore, software citation principles (Smith et al., 2016; Katz  
 482 et al., 2021) have been established to precisely identify software in publications. They require that  
 483 software mentions in scholarly articles are accompanied by additional information allowing the unique  
 484 identification of the actually used software, information that is often missing in practice (Howison and  
 485 Bullard, 2016; Du et al., 2021; Schindler et al., 2021b). Here we employ the following definitions for  
 486 additional information about software as defined by Schindler et al. (2021b). *Developer* describes the  
 487 person or organization that developed a software while *Version* indicates a defined state in the software  
 488 life-cycle, typically identified by a version number, *Release* indicates a defined state in the software  
 489 life-cycle by using a date based identifier, and *Extension* indicates different function ranges for the same  
 490 base software such as professional and basic versions. *URL* gives a location for further information and  
 491 download, *Citation* provides a formal, bibliographic citation, and *License* covers the permission and terms  
 492 of usage. Lastly, *Abbreviation* gives a shortened name for a software while *Alternative Name* provides a  
 493 longer name. All additional information is related to the specific entity it describes. In most cases this is a  
 494 software, but licenses can also be specified by versions, URLs and abbreviations, while developers can be  
 495 closer described by URLs and abbreviations.

#### 496 ***Datamodel and RDF/S Lifting***

497 In order to ensure interpretability and reusability, extracted data is lifted into a structured KG based on  
 498 established vocabularies. KGs represent a meaningful way to semantically structure information in an  
 499 unambiguous way and provide a reasonable approach to make data accessible for later reuse. In particular,  
 500 KGs enable the FAIR publication of research data.

501 The data model of the KG is depicted in Fig. 5. It can be subdivided into different areas that represent  
 502 different types of information. Bibliographic information about articles, journal and authors (depicted  
 503 in violet color) is represented by employing terms from the Bibliographic Ontology (bibo) (D'Arcus  
 504 and Giasson, 2009), Dublin Core Metadata Initiative Terms (DCT) (DCMI Usage Board, 2020), Simple  
 505 Knowledge Organization System (SKOS) (Miles et al., 2005), and schema.org (Guha et al., 2016). The  
 506 representation of entity mentions that were automatically extracted from the texts (orange color), is  
 507 mainly built upon the NLP Interchange Format (NIF) (Hellmann et al., 2013) and Datacite (Peroni  
 508 et al., 2016). Disambiguated software are represented by *Software* from Informatics Research Artifacts  
 509 Ontology (IRAO) (Bach, 2021). For the metadata of software we examined dedicated vocabularies and  
 510 ontologies including DOAP (Description of a Project) (Wilder-James, 2018), SDO (Software Description  
 511 Ontology) (Garijo et al., 2019), SWO (Software Ontology) (Malone et al., 2014), OS (OntoSoft) (Gil  
 512 et al., 2015), and Codemeta (Jones et al., 2017) (including their crosswalk), but did not use those terms  
 513 as they do not represent the textual information but the real entities. For clear separation of fact and  
 514 prediction we opted to not create entities from our mentions but model the mentions as they are and  
 515 provide information inferred on top of them in the form of reification statements (green color). Whenever  
 516 we were not able to identify existing vocabularies that allow the representation, we introduced new terms

**Figure 5.** Datamodel of the Knowledge Graph representing extracted software mentions and their related information. For reasons of conciseness some details are left out.

under the prefix `skg` (<http://data.gesis.org/softwarekg/vocab/>). This was necessary for modelling the information, mention and software types.

Articles and mentions are central entities of the KG. For each piece of information extracted from an article (`schema:ScholarlyArticle`) such as software, version, developer `nif:String` was used to represent the mention. The type of a mention is noted using the `skg:informationType` property (yellow). A software mention has no `skg:informationType` instead it has a software type (`skg:softwareType`) and a mention type (`skg:mentionType`, yellow). To represent relations at the textual level, we introduced predicates for each possible relation. The mention of a software, for instance, refers to the corresponding version via `skg:referredToByVersion`.

In order to indicate different degrees of probabilities for information out of all extracted information for each software we use reification statements (`rdf:Statement`) instead of domain entities. Confidence values based on the frequency within and across articles are used to provide a measure of certainty. Formally, let  $I_{r,x}$  be the set of all forms of a piece of information for a given relation  $r$  and software  $x$ . Further, let  $D$  be the set of all articles and  $m_{r,a,x}$  the mapping of a piece of information  $a \in I_{r,x}$  to  $x$  under the relation  $r$ , we then define the confidence score  $c_{m_{a,x}}$  as given in:

$$c_{m_{a,x}} = \frac{1}{|\{d \in D \mid m_{r,b,x} \in d, b \in I_{r,x}\}|} \cdot \sum_{d \in D} \frac{|\{m_{r,a,x} \in d\}|}{\sum_{b \in I_{r,x}} |\{m_{r,b,x} \in d\}|}, a \equiv b.$$

$a \equiv b$  signals that both,  $a$  and  $b$  represent the same type of information, e.g., name or developer. This way we achieve a ratio based fair weighting on mention level and on document level. All values range from 0 to 1 and also add up to 1.

**Additional Information Sources** SoftwareKG was build upon data from PMC making use of the PMC OA JATS XML data set as structured information source for article metadata. Data from PubMedKG (Xu et al., 2020) was integrated to allow bibliometric and domain specific analyses. In particular, we used PKG2020S4 (1781-Dec. 2020), Version 4 available from <http://er.tacc.utexas.edu/datasets/ped>. It includes Scimago data on journal H-index, journal rank, best quartiles as well as their domains and publishers. Moreover, it includes citation information for articles in Pubmed from Pubmed itself and Web of Science. <https://www.overleaf.com/project/6090cd69c48da20735eb0ddc> The mapping from PMC article identifiers to PubMed identifiers was done based on the Pubmed's mapping

Model Compare ( $n=499$ )

Gradient Clipping	1.0

**Table 6.** Selected hyper-parameters for  $M_{SB,sw,opt}$  fine-tuning.

service, available at <https://www.ncbi.nlm.nih.gov/pmc/pmcftopmid/>. Specifically, we used their CSV table to match the PMC-ID in Pubmed Central with PM-ID from PubmedKG.

Journal specific information vary over time so we modelled them in an *skg:JournalInfo*-entity that encapsulates information per year. Citation data are integrated in two ways: First all citations between PMC Open Access articles are inserted as *schema:citation* in the KG and second the number of overall citations an article received in Pubmed are included as a citation count. This allows analyses based on citation counts, but also provides a basis to identify particular citations paths.

## RESULTS: INFORMATION EXTRACTION PERFORMANCE

### Entity Recognition and Classification

Performance for software recognition on development set, used to select the best model, is summarized in Table 5. All values are provided by mean and standard deviation for repeated training to assess the effect of randomization in the training process of deep learning models. We found that both BERT based models perform better than  $M_{L,sw,opt}$  in both precision and recall. As described above,  $M_{SB,sw,plain}$  and  $M_{BB,sw,plain}$  were initially compared with the same set of default hyper-parameters and only the best of the two models was optimized. In the initial comparison,  $M_{SB,sw,plain}$  showed better performance than  $M_{BB,sw,plain}$  with respect to recall and was therefore selected. We found that hyper-parameter optimization for  $M_{SB,sw,plain}$  improved performance further, especially in terms of recall. A detailed overview of all performed hyper-parameter tests for the Bi-LSTM-CRF ( $M_{L,sw,-}$ ) is given in Tables A1 to A6 and for SciBERT ( $M_{SB,sw,-}$ ) in Tables A7 to A10. The chosen hyper-parameter configuration for  $M_{SB,sw,opt}$  is summarized in Table 6. It outperforms SOMESCI baseline by 7 pp on the development set and is selected as the best model for the task.

The test set performance of  $M_{SB,sw+info,opt}$  on all classification tasks is summarized and compared to the baseline in Table 7. Software extraction and overall entity recognition perform well with respective FScores of 0.883 ( $\pm 0.005$ ) and 0.885 ( $\pm 0.005$ ). The entity types Extension, Release, and AlternativeName, for which the fewest data samples are available, show a lower performance compared to the other entities. Software types are recognized with a good overall performance of 0.796 ( $\pm 0.008$ ). Especially the types Programming Environment and Operating System are recognized with high performance. The software type Application is also recognized well, but PlugIn shows a lower performance of 0.5 ( $\pm 0.023$ ). Software type classification also performs well with 0.806 ( $\pm 0.01$ ). Here, mention type Allusion is the most challenging target with 0.522 ( $\pm 0.038$ ) FScore, while all other targets are extracted with a satisfactory performance.

Deposition	0.71 ( $\pm 0.058$ )	0.821 ( $\pm 0.018$ )	<b>0.761</b> ( $\pm 0.036$ )	0.65	28
Allusion	0.603 ( $\pm 0.058$ )	0.464 ( $\pm 0.046$ )	<b>0.522</b> ( $\pm 0.038$ )	0.29	71
Usage	0.832 ( $\pm 0.013$ )	0.883 ( $\pm 0.011$ )	<b>0.857</b> ( $\pm 0.007$ )	0.80	438
<b>Mention Type</b>	0.794 ( $\pm 0.016$ )	0.823 ( $\pm 0.01$ )	<b>0.806</b> ( $\pm 0.01$ )	0.74	590

**Table 7.** Software mention extraction results for  $M_{SB,sw+info,opt}$  in comparison with SOMESCI baseline as reported by Schindler et al. (2021b), where  $n$  denotes the number of samples available for each classification target. Please note that the baseline model applies hierarchical classifiers on the task and does not adjust the performance for error propagation between the initial classification of software and all other down-stream tasks. Therefore, all baseline results except for *software* are prone to overestimate performance when compared to the given results.

## Relation Extraction

The results for RE by the Random Forest as well as the original SOMESCI baseline on both, development set and test set are given and compared in Table 8. In summary, high recognition rates with .94 FScore are observed, showing improvements resulting from our extension and optimization to the baseline. At the level of the individual relation types, high FScores ( $> 0.9$ ) are observed for all types except for Release  $F1=.82$ , PlugIn  $F1=.78$ , and Specification  $F1=.71$ . This indicates that relations between two software entities, i.e., PlugIn and Specification, are particularly challenging classification targets.

## Software Disambiguation

As described above, the disambiguation first uses a perceptron model to estimate linking probabilities between entity pairs and afterwards uses the probabilities for hierarchical clustering. The optimized perceptron predicted links between software entities with a Precision .96, Recall .90, and FScore .93. These values were estimated on test dataset with a threshold of  $t=0.5$  based on the sigmoid output. The perceptron performance does influence the final performance, but through the performed clustering entity pairs  $p_{link}(E_A, E_C) < t$  can still be linked even if they have not been predicted by the perceptron through a chain of closer entities:  $p_{link}(E_A, E_B) > t$ ,  $p_{link}(E_B, E_C) > t$ . Therefore, evaluation of the perceptron alone does not allow to make statements about disambiguation quality.

For the actual hierarchical clustering based on single linkage performance was estimated with a Precision of .99, Recall of .96, and FScore of .97 at a optimal threshold of  $t=0.00347$  for clustering all gold label data in a common features space with all extracted data. The SOMESCI baseline results are reported with Precision of .99, Recall of .96 and FScore of .97, but as noted above they cannot be compared to the results reported here. The small threshold is a clear indicator of how densely populated the feature space is considering all extracted software mentions. In total 605.364 clusters of software were generated.

Label	Development Set					Test Set

**Table 8.** Summary of RE results for both development and test set. SOMESCI represents baseline FScores for comparison. P=Precision, R=Recall, F1=FScore, n=Number of samples per relation.

## RESULTS: ANALYSIS OF SOFTWARE MENTIONS

### KG Statistics

The KG was constructed from subject-predicate-object 301,825,757 triples, representing 11.8 M software mentions in more than 3.2 M articles in 15,338 journals from 2,136 publishers. On average, each journal contains 210 articles, ranging from 1 article to 239,962 articles in the journal PLoS One.

For ~8.7 K journals (containing 2.8 M articles, 86.7%) additional information, including citations, research domain and journal ranks was identified from integrating data of the PubMed KG (Xu et al., 2020). For almost 2.5 M articles a citation count different from 0 could be found. In summary, 303 categories from 27 top level domains were found, see Table 9.

A detailed overview of article and journal frequencies per research domain is provided in Table A11. As expected from a repository of Open Access articles from Biomedicine and Life Sciences, the distribution of journals and articles is skewed towards Medicine, as ~1.9 M articles from 4,455 journals are related to Medicine, while only 2,178 articles from 181 journals are from the Economics. However, the relative amount of articles not directly related to medicine is relatively high (more than 30%). This includes disciplines such as Computer Science (~77 K articles from 396 journals) and Mathematics (~39 K articles 364 journals), but also Business (~3 K articles from 173 journals) and Arts and Humanities (~9 K articles from 469 journals).

### Software Mentions

By employing disambiguation, different spellings of the same software were grouped, resulting in 605,362 unique software instances with 1.08 different spellings and 19.48 mentions for each on average. A highly skewed distribution of mentions per software can be observed, where about 10% of the software account for about 90% of the software mentions across all articles. Fig. 6 illustrates this distribution graphically. Table 10 provides an overview of the 10 most frequent software, including their absolute and relative number of mentions across all articles. Furthermore, the number of articles containing at least one mention of the respective software is given in the column # Articles. With 539,258 respectively 469,759 mentions, SPSS and R are mentioned most frequently across all articles, where 440 different spellings were observed for SPSS and only 1 for R. The different spellings for SPSS include common names such as “SPSS” (78.4%), “SPSS Statistics” (10.8%), and “Statistical Package for the Social Sciences” (3.8%), but also those with spelling mistakes such as “Statistical Package for the Special [sic] Sciences”.

Fig. 7 illustrates the top 10 software per research domain. From the plot, domain-specific differences can be observed. No domain is consistent with the domain-independent view (see Table 10), and each domain is characterised by a different distribution of the top 10 software. While SPSS (top 1 for 13/27) and R (top 1 for 6/27) together represent the top mentioned software in more the 70% of the domains, Excel, BLAST, Prism, and ArcGIS (each 1/27) are the top software in Economics, Energy, Immunology, and Business, respectively. The software SHELXL, SHELXS, SAINT, and SHELXTL play a mayor role in Chemistry, Materials, and Physics, taking ranks among 1–5 in each of these domains, but are not

Main research domain	Research subcategories (excerpt)
<b>Physics</b> and Astronomy	Acoustics and Ultrasonics, Astronomy and Astrophysics, Atomic and Molecular Physics, and Optics
<b>Chemistry</b>	Analytical Chemistry, Chemistry (miscellaneous), Electrochemistry
<b>Social Sciences</b>	Anthropology, Archeology, Communication

<b>Health Professions</b>	Chiropractics, Complementary and Manual Therapy, Health Information Management
<b>Chemical Engineering</b>	Bioengineering, Catalysis, Chemical Engineering (miscellaneous)

**Table 9.** Overview of the 27 main research domains and 3 of their sub categories that were used to group journals. Bold font highlights the abbreviation of the respective research domain used here.

among the top 10 in any other field. Several programming environments are listed among the top 10 software, including R, Python, Java, C, and C++, most prominent in Mathematics, Engineering, and Computer Science. Material Science plays a special role, when it comes to domain specific software, as the Operating System Windows is the only software that is shared with most other domains, while the remaining software allows a unique characterization. Regarding operating systems, Windows is frequently mentioned in all research domains, except for Earth and Planetary Sciences and Energy. The Linux operating system, in contrast, is ranked 5th in Mathematics, 7th in Decision Sciences, and 9th in Computer Science, respectively. The source code and data repositories GitHub and FigShare are listed among the top 10 software in Decision Science with rank 5 and 9.

## Article Level Statistics

On the article level, we observe that each article contains 3.67 software mentions on average, ranging from 0 software mentions for 1,301,192 articles to a maximum of 673 mentions for one article. Looking at the number of articles per year, it can be observed that the relative number of articles mentioning at least one software increases over all articles. Fig. 8 (blue line) illustrates this graphically. Considering those articles only, a similar trend can be observed from the mean frequency of software mentioned within one article (Fig. 8, green line). Due to the low number of software mentions before 1997 (blue line), the estimation of mean software frequencies per article is less reliable before 1997. In 1997, a steep increase in the number of articles with software can be observed which remains constant until 2000. From 2001 another increase until 2008 can be observed, which is followed by a phase where the relative frequency of articles with software increases more slowly until 2021. From 2007 more than 50% of the articles contain

**Figure 6.** Cumulative distribution of software mentions per unique software. Left (bottom) scale gives the relative values, whereas right (top) scale provides the absolute numbers.

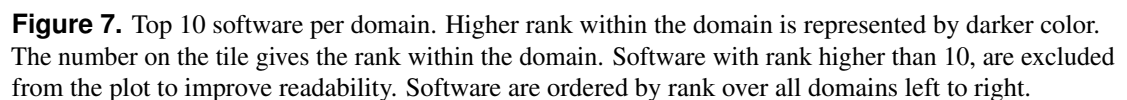

Software	Absolute #	Relative #	# Articles	# Spellings
SPSS	539257	4.57	466511	440
R	469758	3.98	235183	1
Prism	220178	1.87	189580	1
ImageJ	228141	1.93	144738	83
Windows	140941	1.19	127691	6
Stata	147588	1.25	118415	141
Excel	151616	1.29	118083	54
SAS	140215	1.19	112680	215
BLAST	271346	2.30	104735	383

**Table 10.** Information about 10 most frequent software mentions across all disciplines together with their absolute and relative number of mentions, the number of articles that contain at least one mention and the number of spelling variation that could be disambiguated.

at least one software, increasing to almost 75% in 2021. A notable decrease was observed for 2020. With respect to the number of software per article (green line), the frequency remains at a constant level of ~4 from 2005. Standard deviations are omitted but are on a high level between 2 for low mean values and 4 for higher means. To determine the effect of the year on the number of software per article, a linear model was fitted to explain the binary logarithm of the number of software per article by the interaction of year and domain. We found a significant ( $p < 0.001$ ) but small influence of the year (slope=0.017,  $S_e=0.0006$ ,  $R^2=0.06525$ ), when considering the interaction with the domain.

When looking at the relative amount of articles with software per research domain, we found notable differences between the individual domains. Fig. 9 (blue line) illustrates those differences graphically. While in Arts and Economics only 40% of the articles contain software mentions, in Mathematics, Agriculture and Biological Sciences, and Decision Sciences, more than 80% of the articles mention at least one software. The number of different software per article draws a similar picture (Fig. 9, green line), ranging from values of 2 or 3 in Arts, Economics, and Dentistry to values above 8 for Computer Science, Mathematics, and Decision Science. A one-way ANOVA revealed these differences to be significant ( $p < 0.001$ ,  $F_{26,3468692}=7950.1$ ).

Comparing the amount of articles with software mentions with journal rank and citation count per year, similar observations were found. Both graphs are illustrated in Fig. 10. The graph illustrates the ventiles (20-quantiles) of the journal rank, grouped by domain to prevent domain specific biases due to higher journal ranks. In detail, in the first step, for each domain, the journals were distributed according to their rank ventiles and the resulting ventiles were then merged across all domains. A similar approach was chosen for summarizing the articles via citation count ventiles. Please note that while for journal rank based analysis all ranked journals could be considered, for citation count analysis we restricted the analysis to all articles published before 2020 to reduce a bias towards 0 citations. When considering the journal rank, we found that almost 75% of the articles on the lowest rank contain software mentions, followed by a strong decrease for the next two ventiles (blue line). For the remaining ventiles an increasing trend up to almost 80% for higher journal ranks could be observed. When considering the amount of software per article, an initial high-point and decrease for the four lower journal ranks could be observed followed

Similarly, a high value followed by a slight decrease could be observed for the relative number of articles mentioning at least one software per citation count per year (blue line), even though the pattern is not that distinctive. After reaching the minimum frequency of articles containing software mentions in the 2nd ventile, the graph shows an increasing trend for the remaining ventiles, with a slow decrease for the last seven ventiles. The maximum frequency of articles with software mentions is reached at 13th citation count ventile. A linear model to explain the relation between binary logarithm of the number of software per article and the citation count per year grouped by domain revealed a small but significant ( $p < 0.001$ ) effect (slope=0.01,  $S_e=0.0003$ ,  $R^2=0.065$ ).

Considering the articles that contain software mentions, we analysed the amount of information necessary to identify the particular software provided for each software mentioned within one article. For each unique software (which might be referred to multiple times within the same article) we examined whether the version and/or the developer was mentioned within the article. Moreover, the frequency of formal citation (a citation referring to the bibliography of the article) was investigated.

PeerJ Comput. Sci. reviewing PDF | (CS-2021:10:66517:1:0:NEW 19 Nov 2021)

**Figure 8.** Blue: Relative frequency of articles with at least one software mention per year. Green: Absolute mean frequency of unique software mentioned per article with at least one software mention per year. Please note that standard deviations are at the same level as the actual average values but are omitted here for reasons of readability.

accompanied with version and developer remained constant since 2009.

Considering domain specific software citation habits, Fig. 12 illustrates the amount of information provided per software over different research domains. Mathematics, Decision Science, and Computer Science provide the least additional information with down to 20% of mentions, but all three have comparably high numbers of formal citation with around 40%. Dentistry, Nursing, and Materials, in contrast, provide most additional information with up to 70% of mentions but low numbers of formal citations with down to 5%. Nursing and Dentistry also have the highest share of software together with version and developer. In general, citation completeness is not better in domains that use most software.

With respect to journal rank, a slight negative correlation between the rank ventile and the amount of additional information can be observed. Fig. 13 illustrates this relation graphically. In contrast, a positive correlation between amount of formal citation and journal rank can be seen. While for low ranked journals, most software are accompanied with developer (almost 70%), this decreases with rising journal rank, reaching a first local minimum at rank 8 and the absolute minimum for the journals with the highest rank. The use of formal citations, in contrast, shows an increase from the lowest ranked journals from ~10% to the journals with the highest rank with about 30%.

Considering the citation rank (see Fig. 14), a slight increase in provided additional information could be observed in the first four ventiles and a slight decrease in the last four. No notable difference could be observed for the remaining citation ventiles. For formal citation, a slight increase over the ventiles can be observed, starting with 20% and reaching up to over 25%.

## Types of Software Mention

For each software mention, the KG contains information about the type of mention and the type of software. The most frequent type of software is Application with 84.49%, followed by Programming Environment with 7.29%, PlugIn with 6.27%, and Operating Systems with 1.95% of the mentions. When looking at the disambiguated software, 88.52% of the software are Applications, 10.74% PlugIns, 0.41% Programming Environments, and 0.33% Operating Systems. With respect to the type of mention, we observed that most mentions of software reflect Usage with 82.31%, whereas 15.09% represent Allusion. Only 2.01% (0.6%) of the software mentions represent Creation (Deposition) statements. Table 11 gives a more fine-grained overview of the relation between type of mention and type of software. The mention type Usage is prevalent over all software types and the software type Application over all mention types. Furthermore, we found that the relative frequency for both Creation and Deposition is 0 for Operating Systems and Programming Environments. When looking into domain specific differences, it can be observed that Mathematics (51.4%), Engineering (55.0%), and Computer Science (55.0%) have the lowest share of usage statements, while disciplines such as Energy (90.2%), Materials Science (93.1%), Nursing (93.3%), Dentistry (93.9%), and Veterinary (95.7%) have the highest share of usage statements. The opposite trend can be observed for software Allusion statements, beginning with Veterinary (3.9%) to

**Figure 9. Blue:** Relative frequency of articles with at least one software mention per research domain. **Green:** Average number of different software mentioned per article with at least one software mention given by research domain. Note that standard deviations are large (similar to average values) and are omitted here.

	Allusion	Creation	Deposition	Usage	Overall
Application	13.95	1.80	0.56	68.14	84.49
OperatingSystem	0.26	0.00	0.00	1.69	1.95
PlugIn	0.47	0.17	0.04	5.58	6.27
ProgrammingEnvironment	0.40	0.00	0.00	6.88	7.29
Overall	15.09	2.01	0.60	82.31	100.00

**Table 11.** Overview of the relative frequency of software and mention types over all software mentions, for all combinations. Note that overall numbers do not necessarily sum to 100 due to rounding issues.

743 Mathematics (40.7%). Software Creation statements have the highest proportion in Mathematics with  
744 6% of all mentions, followed by Engineering (5.4%) and Computer Science (5.4%). In Dentistry and  
745 Veterinary only 0.3% and 0.4% are Creation statements. Decision Sciences (1.8%), Mathematics (1.7%)  
746 and Computer Science (1.5%) have the highest share of deposition statements. In Materials Science and  
747 Veterinary in contrast, less than 0.1% of the software mentions are Deposition statements.

748 The software type PlugIn plays a special role, as it can only be used together with another software,  
749 requiring the mention of both, the host software and the PlugIn. Table 12 lists the top 10 host software  
750 together with the amount of PlugIns identified for this software, the number PlugIn mentions for the  
751 software and the top 5 PlugIns. We found that the Programming Environment R is with 19,442 distinct  
752 PlugIns by far the software with the most PlugIns, followed by Matlab and Python. As most frequently  
753 mentioned PlugIns for R we found Bioconductor, ggplot2, lme4, vegan, and DESeq2 which together  
754 account for 17,2% of all PlugIn mentions. Note that the two different spellings *Python* and *python* were  
755 not linked together but reflect a similar distribution of PlugIns.

## 756 Software Creation and Deposition

757 Software Usage and Deposition statements are often accompanied by URLs to provide a location to  
758 access a software. This is especially interesting to make a software findable for the scientific community.  
759 Table 13 shows the most common domains of URLs mentioned in combination with software Usage and  
760 software Depositions. Usage domains (right) can correspond to specific software, for instance, `blast.ncbi.nlm.nih.gov` or `r-project.org` for BLAST and R, but also to software repositories such  
761 as Github and specific software package repositories such as CRAN `cran.r-project.org`. For  
762 Depositions (left) we found that most of the URLs point to source code and software repositories. Most  
763

**Figure 10. Blue:** Relative frequency of articles that contain at least one software mention per rank of bibliometric measure. **Green:** Average number of different software per article per bibliometric measure. Note that the high standard deviation (at the same level as average values) are left out to increase readability.

Software	# PlugIn	# Mention	Top 5 PlugIn incl. % of mentions
R	19,442	220,750	Bioconductor (4.79%), ggplot 2 (3.63%), lme 4 (3.21%), vegan (3.09%), DESeq 2 (2.52%)

SPM	521	2,671	DARTEL (20.03%), MarsBaR (9.51%), Marsbar (2.91%), CONN (2.61%), DPARSF (2.54%)

**Table 12.** Most frequent host software, i.e., mentioned together with a PlugIn, in combination with the most frequently used PlugIns for each of them. # PlugIn: distinct, disambiguated PlugIns; # Mention: overall PlugIn mentions.

frequent is Github ([github.com](https://github.com)) with 14% of overall URLs, but other public repositories such as SourceForge, BitBucket or Google Code are present as well as repositories focused on packages such as CRAN and BioConductor.

Another aspect of recognizing software Creation and Deposition statements in articles is that it allows

**Figure 11.** Distribution of software completeness per year with the percentage of unique software per article that is cited with provided additional information. The colored bars represent the different levels of completeness while the line chart separately indicates how many software mentions were accompanied by a formal citation. The numbers at the top of the bars represent the absolute number of software considered per year.

**Table 13.** Top 10 most frequent URLs accompanying software Deposition and Usage statements together with their absolute and relative frequencies.

to identify journals that are most frequently used for the description of new software. By analyzing the relative number of articles per journal that contain either a software Creation or Deposition statement, we were able to find the most active journals when it comes to software description. Considering only journals with at least 10 articles, we found that with 90% of the articles containing software Creation statements, the *Proceedings of the VLDB Endowment* is ranked highest among journals introducing software. It is followed by the journal *Source Code for Biology and Medicine* with 84.4%, *Database: the journal of biological databases and curation* with 74.4%, and the *Journal of Open Research Software* and *Bioinformatics* with 72.7% and 70.8%, respectively. The journal *Source Code for Biology and Medicine* contains the most articles with software Deposition statements (64.7%), followed by *Journal of Open Research Software* and *Neuroinformatics* with 54.5% and 47.1%, respectively. From 15,388 journals, only 3,622 journals contain at least one article with either Creation or Deposition statements.

DISCUSSION

Reliable Method for Software Mention Extraction

Information extraction is based on reliable ground truth data from SOMESCI (IRR  $F=.93$ ,  $\kappa=.82$ ). In combination with state-of-the-art language models for scientific articles such as SciBERT, we achieve state-of-the-art performance for software mention extraction in scientific articles. Regarding software

**Figure 12.** Distribution of software completeness per research domain. The numbers at the top of the bars represent the absolute numbers of software considered per domain. Please note that articles may belong to multiple categories.

**Figure 13.** Distribution of software completeness per ventile of journal rank per research domains. The numbers at the top of the bars represent the absolute numbers considered per ventiles.

**Figure 14.** Distribution of software completeness per ventile of citation count per research domain. Note that only articles published before 2020 were included to prevent a bias towards lower citation ventiles.

recognition, the SOMESCI baseline was outperformed by a notable margin raising performance to  $F=.88$  from  $F=.83$  by 5 pp. This also represents an increase over the previous automatic approaches by Pan et al. (2015) with  $F=.58$ , Duck et al. (2016) with  $F=.67$ , Lopez et al. (2021) with  $F=.74$  and Schindler et al. (2020) with  $F=.82$ , however, as prior work was based on a different data basis, the results are not directly comparable. With respect to the chosen NER architecture, SciBERT achieved superior recognition rates when compared with Bi-LSTM based models, illustrating the effectiveness of SciBERT for mining scholarly documents. Interestingly, Lopez et al. (2021) report notable lower performances for both architectures, which we believe results from the less reliable input including PDF conversion artifacts and ground truth annotation.

Regarding the identification of additional information ( $F=.89$ , SOMESCI baseline  $F=.85$ ) as well as software type ( $F=.80$ , SOMESCI baseline  $F=.78$ ) and mention type ( $F=.81$ , SOMESCI baseline  $F=.74$ ), we achieve better performance than baseline results, especially considering that the reported results already take error propagation into account, which is not the case for baseline results. We also achieve better performance for Version, Developer, and URL as reported for the Softcite (Du et al., 2021; Lopez et al., 2021) corpus, however, these results cannot be directly compared due to different training and test data. Moreover, the study presented here is the first that classifies software mentions according to both, software and mention type. However, we found that software type PlugIn and mention type Allusion were extracted with lower performance as other types. In both cases the lower performance is mainly due to confusion with another class (Application and Usage) with corresponding higher prior probability but a difficult to distinguish context. This is consistent with the results of the manual annotation performed for SOMESCI (Schindler et al., 2021b), where annotation IRR was also found to be lowest for these classes.

RE and disambiguation for software mentions has, to the best of our knowledge, not been evaluated as part of any scientific investigation of software mentions in scholarly publications besides the SOMESCI baseline. We improve RE performance by 6 pp from  $F=.88$  to  $F=.94$ . RE performs well for additional information related to software, but it is challenging ( $F=.71-.78$ ) to predict relations between software entities such as the *plugin-of* relation. This was expected since, by definition, additional information always is related to another entity while two software entities are not necessarily related to each other. Consequently, relations between software are rare compared to the overall number of software mentions. It should also be noted that both, baseline and our reported results, do not take error propagation from entity recognition to RE into account. Overall, we achieved superior recognition rates compared to previous, automatic, large scale analyses of software mentions in scholarly publications and conclude, thus, that software mentions and additional information extracted by our pipeline are more reliable.

With respect to disambiguation, it has to be noted that previous large scale analyses did not consider spelling variations but only summarized software mentions with equal (or similar) spellings. As this is the first study to use disambiguation methods for software mentions, comparison to state-of-the-art results is not possible. However, the disambiguation baseline performance for SOMESCI of  $F=.97$  was

achieved, while considering a much denser feature space. In small data sets, only few spelling variations (and other features used for disambiguation) of software exist; this number increases with the size of the data set. This means that finding reliable boundaries between different software gets harder with increasing size of the data set as rare spelling variations (and other features) of software with similar names tend to overlap stronger with increasing amounts of data. In our case, the training data set contains 3,756 software mentions from 637 different software while information extraction resulted in almost 12 M software mentions. To recreate this effect for the training data, we included a large set of augmented, fictional software names. With respect to evaluation, the negative effect of increasing sample size on the ability of finding reliable boundaries between different software prevents the transfer of quality statement from training to inference dataset. To counteract this effect, we included the manually disambiguated training data in the inference dataset, determined the clustering threshold, and evaluated the quality based on those samples. Same as for RE, it should be noted that error propagation from the previous information extraction steps influence disambiguation performance. The additional augmented samples simulate the effect of false positives, but we cannot estimate to what extent they are successful at suppressing resulting errors. False negative samples do in practice directly influence linking quality.

Due to computational and space complexity we chose a single linkage-based clustering, which is known for semantic drift away from cluster means, but enables an efficient implementation when distance between all pairs is pre-computed and sorted up to a given threshold. Average linkage would have required to re-compute the average distance of all clusters in each step. An initial evaluation showed only marginal differences between single and average linking based clustering for disambiguation, which seemed sufficient for the task at hand. Overall, disambiguation provides reasonable results; 440 different spellings for SPSS<sup>4</sup>, have for instance been discovered. For the different spellings python and Python (see Table 12), however, no common cluster could be determined. While this clearly represents an error when considering the string only, our machine learning based distance additionally considers the context and accompanying entities such as developer and URL. We believe that the reason here is the low number of spelling variations that prevent the semantic drift to counteract misleading linking probabilities. This in consequence would mean that more frequent software (with many different contexts and spelling variations) are more likely to be disambiguated than less frequent software (with fewer contexts and spelling variations), which may have had a reinforcing effect on the power law distribution of mentioned software. For software with more frequent spelling and context variations, in contrast, this might result in more false positives and thus overestimate the software use. For Excel, 54 spelling variations were found that represent 152 K mentions. From those only about 150 K mentions (from 13 different spellings) can be considered as correctly classified. The remaining mentions contain software such as Firefox (1162, 0.7%) or F (185, 0.1%). A similar phenomenon could be observed for Stata. While disambiguation performance is satisfactory the algorithm can be improved in future work, for instance, by including information on PlugIns provided with software names after an initial disambiguation of the PlugIn names. However, the number of considered contexts would have to be increased or contexts summarized because rare features such as PlugIns are unlikely to be present in the 6 context samples that are currently used, which would lead to higher run-time.

### SoftwareKG: Knowledge Graph of Software Mentions

SoftwareKG represents the largest dataset of software mentions and related metadata in scholarly publication. It contains 11.8 M software mentions from over 605 K different software automatically extracted from more than 3 M Open Access articles from PMC. Moreover information from PubMedKG was integrated to allow bibliometric analyses. The KG was created by re-using established vocabularies for data representation, such as schema.org, BIBO, and DCT and is available as JSON-LD under Creative Commons Attribution at Zenodo (Schindler et al., 2021a). The published version of the KG only contains information available under open licenses. As this is not the case for most of the bibliometric data, those parts were excluded from publication.

SoftwareKG consists of over 300 M triples describing the properties and relations between more than 55 M resources. A summary of the properties of SoftwareKG is given in Table 14. In SoftwareKG, we employ frequency-based confidence values to provide a transparent way to analyse errors that originate from information extraction or author spelling variations. For names, developers as well as software type and other information we included those confidence values in the reification statements to allow further

analyses.

SoftwareKG facilitates the large-scale analysis of software mentions in scholarly publications and allows to give insights into the role of software in science. A tutorial to recreate all tables and figures from the KG is included in the supplementary material<sup>5</sup>. This article contains first analyses and sketches the potential for more elaborate studies. This includes the creation of an impact measure for scientific software but also to provide a software mapping for science in general such as swMath (Greuel and Sperber, 2014) for Mathematics.

## The Role of Software in Science / PMC

### Software Mentions

With an average of 3.67 software mentions per article, our result confirms previous studies, ranging from 2.6 (Schindler et al., 2021b) to 3.2 (Howison and Bullard, 2016) to 5.5 (Duck et al., 2016) in different subsets of PMC. With over 605 K, the number of different software from over 11.8 M mentions is high, given that 3.2 M articles were investigated. This number probably overestimates the actual number of software used in science, due to errors from information extraction and disambiguation. The distribution of software mentions per software shows that only few software are used on a huge number of articles and thus play a major role in science. This distribution partly confirms the general trend but shows even higher skewness as previously reported statements about the distribution of software mentions in scholarly articles (Howison and Bullard, 2016). This amplified trend could be the result of software name disambiguation which was not applied in previous studies and highlights the importance of considering all spelling variations for software usage analysis. The most frequent software (7 from the top 10) are mainly used for statistical data analysis. A closer look at the domain specific distribution of the top 10 software revealed domain specific differences. The software SHELXL and SAINT, for instance, are most frequently but exclusively used in Chemistry, Materials and Physics, whereas Excel is frequently used in almost all other research domains except for them. The distribution of the top 10 software characterizes all of the analysed domains uniquely. Overall, an increased role of applications that can be controlled via scripts rather than point and click software can be observed. Schindler et al. (2020), for instance, reported that the Programming Environment R superseded SPSS in small excerpt of articles in PLoS One in 2017. While a similar trend can be seen here, the particular ranks did not change yet, see Fig. 15. While SPSS, Excel, and SAS remain constant for the last 5 years, usages of R and Python increased at the relative level. However, when looking at articles from PLoS One only, R replaced SPSS at the top position, which confirms the result and suggests journal specific software preferences.

### Article Level Statistics

The importance of software increased in recent years for both, the actual investigation as well as the reporting within the scholarly publication. This is suggested by the increasing trend of including software

<sup>5</sup><https://github.com/f-krueger/SoftwareKG-PMC-Analysis>

**Figure 15.** Relative and absolute amount of articles per year mentioning the top statistical software.

mentions into the textual description and the increasing number of different software per article. A reason could be the growing complexity of data driven analyses that requires more software to be employed to perform the different types of analyses coupled with a high awareness about transparency and reproducibility in general. The positive correlation between journal rank and number of different software supports this by suggesting strong rigor in the description of the analysis<sup>6</sup>. The positive correlation of the number of software and the number of citations per article indicates a growing appreciation of the traceability of the described research processes. The observed domain specific difference in software usage could reflect the role of data in those domains. While in Arts and Humanities and Economics only few articles mention only few software suggesting an important role of manual data analysis, in Mathematics, Computer Science, Decision Science, and Agricultural and Biological Science many articles mention multiple different software indicating automatic and complex data collection and analysis processes.

### Software Citation Completeness

Citation completeness has not improved over recent years, that is, the information provided to identify the particular software is not provided to full extent. This suggests a lack of awareness about the necessity to understand and reproduce research processes and its requirement for identifying particular software versions. When comparing formal citation, i.e., providing a formal literature reference, with in-text mention, we found contrary trends for both over time and across categories. While we consider in-text citations as complete when version and developer are included, formal citations are always considered sufficient here. Using this definition, only about 38% of the articles in 2020 allow the unique identification of the used software based on the provided information. Software usages in the technical domains use formal citation more frequently in contrast to research domains related to medicine. We believe that the reason here is that the latter more frequently employ other materials and devices and use the same citation style for all research objects other than scholarly publications. With respect to the rank of the journal, we see a growing trend for the usage of formal software citation and a contrary trend in the completeness of in-text software mention. We believe that this supports the statement of increasing rigor in scholarly review and the request for more traceable descriptions in higher quality journals. Again, with growing citation count, the slight increase of formal citation frequency but decrease of citation completeness supports this. In summary, our results about the completeness of software citation indicate that software citation standards, as suggested by Katz et al. (2021) or Smith et al. (2016) have not been adequately

<sup>6</sup>When interpreting the journal rank as an indicator of journal quality and thus for review quality

936 adapted in scholarly publications, yet.

### 937 **Types of Software Mention**

938 Each software mention is classified according to mention type which indicates the reason why the  
939 software was mentioned within the scholarly article and software type that gives information about the  
940 particular kind of software. Analyses of disciplinary differences showed that most software is created and  
941 published by scientists from the technical domains (Mathematics, Engineering and Computer Science).  
942 This reflects the domains with the highest interest in automating complex calculations combined with  
943 the programming knowledge to implement new suited software applications. Further, software allusions  
944 without actual usage are also more common within scholarly publications from those disciplines indicating  
945 more description, discussion and comparison between software entities. On the other hand there are  
946 disciplines which mostly reuse existing scientific software such as Material Science, Nursing, Dentistry,  
947 and Veterinary.

948 When looking at the different kinds of software, we found an increasing trend of using PlugIns over  
949 recent years, see Fig. A1. The relative frequency of Application mentions, in contrast, declined. We see  
950 this as an indicator toward the usage and extension of established software frameworks. With respect to  
951 the host software, we found a notable overlap in the most frequently used software (Table 10) and the  
952 most important host software (Table 12). This includes the Programming Environments R and Matlab, but  
953 also the Applications ImageJ, Stata, and Excel. More than 19 K PlugIns were found for the Programming  
954 Environment R making it the most important host software for scientific investigations. While this  
955 number seems high at first glance, inspecting the two most important package repositories, CRAN<sup>7</sup> and  
956 Bioconductor<sup>8</sup> with 18,312 and 2,042 unique packages<sup>9</sup> indicates these results to be plausible. However,  
957 the comparably low FScores for the identification of PlugIns might have resulted in an overestimation of  
958 less frequent PlugIns. This growing interest in the Programming Environment R and its package universe  
959 was previously investigated (Li et al., 2017; Li and Yan, 2018), some results of which are confirmed here,  
960 in particular we see an overlap for the most frequent R packages.

### 961 **Software Creation and Deposition**

962 By analysing the mention types Creation and Deposition in particular, we were able to identify the most  
963 important targets for the publication of software. On the one hand this includes web services such as  
964 Github for general purpose software and CRAN for R packages, on the other hand software journals.  
965 Specifically designed repositories to host and assign Digital Object Identifiers (DOI) to scientific research  
966 data such as Zenodo are not commonly used for publishing scientific software with a share of <1% of  
967 depositions. While this allows to provide researchers with recommendations on where to publish their  
968 software and/or the corresponding description, it also enables the search for software. Moreover, the  
969 identification of Creation and Deposition allows to track the scientific software landscape with low latency.  
970 It has to be noted that the second most frequent deposition URL is the result of a false software mention  
971 detection and its propagation.

### 972 **Summary**

973 The importance of software in science has been growing in recent years, in both relative and absolute  
974 numbers. The awareness for providing all necessary information to enable the identification of the  
975 particular software by others, in contrast, remains unchanged. Software citation principles have not  
976 been adapted yet in scholarly publications. However, articles in higher ranked journals tend to more  
977 formal software citations instead of in-text citations, which reflects recent software citation recommen-  
978 dations (Katz et al., 2021). Articles in lower ranked journals in contrast provide more complete in-text  
979 citations, i.e., Version and Developer, in general. We identified domain specific software citation habits:  
980 Medicine related domains prefer in-text citation, while technical domains tend to more formal citations.  
981 Domain independent as well as domain specific software is used across most research domains, the top  
982 10 of which represent domain specific characteristics. Most software mentioned in scholarly article are  
983 software for statistical analysis, such as SPSS, R, and Prism. Interestingly, we identified an increased  
984 interest in the usage of PlugIns, which allow the problem specific extension of general purpose software.  
985 The most important representatives of them are the Programming Environments R, MATLAB, and Python.

<sup>7</sup><https://cran.r-project.org/>

<sup>8</sup><https://www.bioconductor.org/>

<sup>9</sup>Package counts for CRAN and Bioconductor were retrieved on October 4th, 2021

Finally, we confirmed Github as a central repository for scientific software, for both publication and re-use, as previously assumed (Russell et al., 2018).

### Limitations of the study

The study presented in this article involves complex data processing and information extraction steps, where each of these is subject to limitation that are discussed in the following.

The articles in SoftwareKG cover a broad range of scientific disciplines, however, the selection of PMC as primary data source implies a bias towards Medicine. While the training data set SOMESCI itself is also taken from PMC, the selection might introduce domain specific biases. Therefore, the trends reported here, might be different if we look at a domain such as computer science in general. For instance, BLAST is the second most used software in computer science in our set, which would likely not be true when looking at computer science in general, as this software is primarily used in Bioinformatics. Another bias in the selection of articles is towards open access, as all article are from the PMC Open Access subset. Researchers choosing to publish under open access might also be supporters of open data movement and therefore have a better awareness for attributing other open work such as software.

For information extraction and disambiguation, we found high performance for all employed machine learning methods. However, it is important to consider error propagation between them. The given evaluation for software and mention type classification does take error propagation into account, but the results for RE and entity disambiguation do not. Therefore, the  $F=.94$  performance for RE might overestimate the true performance as it relies on results of  $F=.885$  entity recognition. For disambiguation we model the effects of false positive entities by data augmentation, but it is hardly possible to tell if this completely suppresses their effect and false negatives do directly influence disambiguation performance. Moreover, evaluation for disambiguation has proven to be challenging and the gold standard dataset alone is no good predictor for performance on large scale entity disambiguation. We, therefore, adjusted our evaluation method to take the large scale data into account, but note that further systematic evaluation is required for entity disambiguation.

Our analyses regarding domains, journal rank and citation count rely on external data and are, thus, influenced by their quality. For instance, only 86.7% of our data was covered by Scimago data on domains and journal rank. Regarding the external citation data we assumed completeness but in case article citations were missing from the list they were not included in the computed citation count. In case one article would miss completely it would be counted with a citation count of 0.

An analysis of the article types (*skg:documentType*) contained in SoftwareKG showed that aside the largest group of research articles it also covers review articles and abstracts, but also case reports or letters and several other categories. For each of the groups we did find publications that cite software, but the prior probability for software mentions across article types differs. Therefore, it is important to note that the reported results are not specific to only research articles but to the distribution of scientific publications indexed in the PMC OA subset. The information about the article type, however, is included in the KG enabling others to analyse these effects.

## CONCLUSION

In this article we presented the largest analysis of software usage in scholarly publications over the longest duration covering articles between 1990 and 2021<sup>10</sup>. Software mentions were identified by automatic information extraction covering NER for software and associated information, software and mention type classification, and RE between software and additional information. Moreover, in difference to previous studies, software names were automatically disambiguated to allow reasoning about software usage even when the same software is referred to by different names. The analysis covers 3.2M articles, mentioning a total of 11.8 M software.

From the extracted information, we created SoftwareKG, the largest KG describing software mentions in scholarly publications. The KG was created by re-using existing vocabularies and published under an Open Access licence to support further research on the role of software in science. SoftwareKG consists of over 300 M triples and contains information about software, accompanying information as well as information about articles, journals, authors, and publishers.

We performed a large-scale analysis on SoftwareKG with respect to publication date, article domain, journal rank and article citation count in order to identify differences and trends in software mention.

<sup>10</sup>SoftwareKG actually contains articles from before 1990, but we restricted most analyses to time between 1990 and 2021

Overall, the results show that software usage has increased over the course of the last 10 years, but we found no change in citation completeness during this time frame. This leads us to believe that there is still a lack in awareness for software citation in science, even so software citation standards have been available and promoted since 2016, e.g., by Smith et al. (2016).

We also identified a trend towards using extendable software architectures instead of stand-alone software, especially in combination with the Programming Environment R. Overall, their design allows an easy extension and offers high flexibility. Especially adding functionality and publishing new packages or PlugIns is facilitated. We could also show this trend by analyzing which infrastructure is used by scientists to publish their software, with Github playing a central role, but CRAN and Bioconductor being especially important in combination with R.

In general, we show that there are many domain specific peculiarities in software usage. We showed that the amount of software usage as well as the most used software per domain and their application purpose varies significantly. Domain specific citation habits are also reflected in preferences to formal and informal software citation, ranging from 5%–40% in formal citation contrasting to 1%–35% software citation completeness with opposing trends.

Overall, we believe that SoftwareKG provides a valuable data source for further investigations about the role of software in science. One finding that should be further investigated is, for instance, the influence of journal rank to software usage in formal citation. The trend could, for instance, be explained by higher review quality and journal policies enforcing better software citation. Further insights could allow to give better recommendations for journals to encourage software citations habits.

In future work SoftwareKG can build the basis to further explore software usage in science, for instance, as a mapping for available software and newly established software. It can also be used to track software usage and establish software impact measures. Furthermore, the investigation of formal software citations should be extended to include the citation targets. Currently, formal citations are recognized, but not further analysed. In the future we need to include a distinction between software citation and software article citation and model citation completeness within formal citations.

## SOFTWARE AND DATA

We implemented all machine learning models for information extraction in Python 3.9.5 (Van Rossum and Drake, 2009), utilizing the following packages: PyTorch 1.9.0 (Paszke et al., 2019) for deep learning models, Huggingface transformers 4.9.1 (Wolf et al., 2020) to load and fine-tune pre-trained BERT models, Gensim 4.0.1 (Řehůřek and Sojka, 2010) for pre-training word embeddings, scikit-learn 0.24.2 (Pedregosa et al., 2011) for implementation of RE models, articlenizer R-14.06.2021 (Schindler, D., <https://github.com/dave-s477/articlenizer>) for preprocessing of scientific articles, and NLTK 3.6.2 (Loper and Bird, 2002) for feature extraction. Moreover, to extract JATS XML meta-data we used lxml 4.6.3 (Behnel, S. et al. <https://github.com/lxml/lxml>) and for knowledge graph construction rdflib 6.0.0 (RDFLib Team <https://github.com/RDFLib/rdflib>). For statistical analysis and generation of figures we used R 4.1.1 (R Core Team, 2021), utilizing tidyverse 1.3.1 (Wickham et al., 2019) for data processing and plotting and SPARQL 1.16 (van Hage et al., 2013) to access the KG interface. To setup a SPARQL endpoint for SoftwareKG we used OpenLink Virtuoso Open Source Edition 07.20.3229 (OpenLink, 2021), available as docker from <https://hub.docker.com/r/tenforce/virtuoso/>.

Source code for construction and analysis is published on Github at <https://github.com/f-krueger/SoftwareKG-PMC-Analysis> and the data for SoftwareKG (Schindler et al., 2021a) itself is available on Zenodo via <https://doi.org/10.5281/zenodo.5553737>. To facilitate reproducibility of our data analysis, a docker file including a suited R environment to execute analyses on SoftwareKG is included.

1257 **APPENDIX**

Wikipedia-Pubmed Word2Vec ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
False	0.853±0.013	0.815±0.02	0.799±0.023	0.745±0.026	0.825±0.007	0.778±0.007
True	0.881±0.009	0.842±0.018	0.786±0.021	0.722±0.008	0.831±0.011	0.777±0.005

**Table A1.** Overview of hyper-parameter results for using a Bi-LSTM-CRF ( $M_{L,sw,-}$ ) with pre-trained word embedding established by Pyysalo et al. (2013). The word embedding is either trained with the model (True) or frozen while training the model (False).

Custom Embedding ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
False	0.863±0.018	0.821±0.017	0.814±0.006	0.764±0.014	0.838±0.01	0.791±0.006
True	0.866±0.017	0.831±0.02	0.797±0.01	0.752±0.015	0.83±0.008	0.789±0.004

**Table A2.** Overview of hyper-parameter results for using a Bi-LSTM-CRF ( $M_{L,sw,-}$ ) with a custom Word2Vec (Mikolov et al., 2013) model trained on all available articles from PMC OA. The word embedding is either trained with the model (True) or frozen while training the model (False).

LSTM Size ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
100	0.864±0.019	0.831±0.017	0.806±0.01	0.752±0.011	0.834±0.008	0.789±0.003
50	0.852±0.02	0.831±0.02	0.785±0.016	0.751±0.023	0.816±0.003	0.788±0.007

**Table A3.** Overview of results for tuning the size of the Bi-LSTM-CRF model.

Downsampling negative sentences ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
.75	0.855±0.022	0.821±0.028	0.82±0.018	0.765±0.015	0.836±0.003	0.791±0.006
.50	0.832±0.03	0.817±0.022	0.804±0.025	0.756±0.017	0.817±0.017	0.785±0.002

**Table A4.** Overview of results for Bi-LSTM-CRF model with respect to downsampling of negative sentences containing no software entities, which leads to a higher relative frequency of software in the training set. Provided numbers indicate the percentage of remaining overall negative samples.

Character dim ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
10-5	0.852±0.023	0.816±0.022	0.805±0.008	0.764±0.006	0.828±0.013	0.789±0.013
10-10	0.854±0.013	0.836±0.015	0.791±0.007	0.75±0.004	0.821±0.006	0.79±0.007
10-20	0.87±0.015	0.827±0.009	0.797±0.014	0.758±0.015	0.832±0.006	0.79±0.004
10-30	0.837±0.018	0.812±0.013	0.81±0.017	0.769±0.01	0.823±0.006	0.79±0.003
25-10	0.863±0.019	0.829±0.016	0.813±0.013	0.762±0.011	0.837±0.008	0.794±0.004
50-10	0.879±0.003	0.841±0.007	0.791±0.004	0.747±0.009	0.833±0.003	0.791±0.008

**Table A5.** Overview of results for Bi-LSTM-CRF model with varying layer size for character feature generation. The first number refers to the size of the character embedding and the second to the size of the character LSTM.

Adding Custom features ( $M_{L,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
with	0.857±0.024	0.828±0.015	0.816±0.013	0.757±0.021	0.836±0.01	0.79±0.005
without	0.866±0.017	0.831±0.02	0.797±0.01	0.752±0.015	0.83±0.008	0.789±0.004

**Table A6.** Overview of results for Bi-LSTM-CRF model if custom rules are included as features. Rules take distant supervision and string based features into account, their implementation details can be found the corresponding code. *with*: using custom features, *without*: not using custom features.

Downsampling ( $M_{SB,sw,-}$ )						
	Precision		Recall		FScore	
	Test	Devel	Test	Devel	Test	Devel
None	0.87±0.009	0.863±0.016	0.879±0.006	0.844±0.009	0.874±0.007	0.853±0.003
.75	0.871±0.016	0.85±0.015	0.899±0.011	0.871±0.011	0.885±0.007	0.86±0.006
.50	0.869±0.018	0.854±0.006	0.882±0.005	0.846±0.008	0.876±0.009	0.85±0.002

**Table A7.** Overview of results for downsampling with SciBERT model with respect to downsampling of negative sentences containing no software entities, which leads to a higher relative frequency of software in the training set. Provided numbers indicate the percentage of remaining overall negative samples.

Dropout ( $M_{SB,sw,-}$ )						
Precision		Recall		FScore		
Test	Devel	Test	Devel	Test	Devel	
0.0	0.87±0.009	0.863±0.016	0.879±0.006	0.844±0.009	0.874±0.007	0.853±0.003
.20	0.888±0.013	0.865±0.01	0.898±0.012	0.86±0.009	0.893±0.01	0.863±0.005
.30	0.881±0.013	0.86±0.014	0.891±0.011	0.865±0.008	0.886±0.011	0.862±0.004

**Table A8.** Overview of applying dropouts to SciBERT fine-tuning. Values provide the percentage of performed dropouts.

LR ( $M_{SB,sw,-}$ )						
Precision		Recall		FScore		
Test	Devel	Test	Devel	Test	Devel	
1e−5	0.873±0.009	0.856±0.006	0.9±0.006	0.861±0.01	0.886±0.004	0.859±0.005
5e−5	0.884±0.008	0.868±0.006	0.897±0.011	0.865±0.012	0.89±0.004	0.866±0.008
1e−6	0.854±0.013	0.837±0.011	0.902±0.016	0.865±0.013	0.877±0.004	0.851±0.003
5e−6	0.849±0.012	0.827±0.008	0.909±0.014	0.871±0.013	0.878±0.011	0.849±0.01

**Table A9.** Overview of adjusting the learning rate for SciBERT fine-tuning.

Gradient Clipping ( $M_{SB,sw,-}$ )						
Precision		Recall		FScore		
Test	Devel	Test	Devel	Test	Devel	
1.0	0.87±0.009	0.863±0.016	0.879±0.006	0.844±0.009	0.874±0.007	0.853±0.003
2.0	0.873±0.004	0.844±0.011	0.885±0.009	0.857±0.013	0.879±0.004	0.85±0.002
3.0	0.866±0.007	0.847±0.008	0.888±0.02	0.849±0.013	0.877±0.007	0.848±0.005

**Table A10.** Overview of performing gradient clipping at different thresholds for SciBERT fine-tuning.

**Figure A1.** Relative frequencies of software types per year.

Main research domain	# Articles	# Journals
