Abstract

Imines and their derivatives are of great interest to organic synthetic chemists due to their involvement as key intermediates which facilitate the construction of nitrogen heterocycles, particularly the formation of alkaloids. Imine formation by condensation of primary amines with aromatic aldehydes and cyclohexanone has been investigated under environmentally-friendly solventless heterogeneous catalysis. An array of different imines was obtained in excellent yields in appreciably short reaction times using Amberlyst® 15 as a heterogeneous catalyst. The latter was used owing to its high commercial availability, recyclability, ease of separation from the reaction mixture, and versatility.

Keywords

Solventless; Amberlyst® 15; Imine synthesis; Heterogeneous catalysis; Aryl/alkyl amines, Easy separation

1. Introduction

Imines are fundamental intermediates in the synthesis of N-containing organic molecules which are biologically active (particularly alkaloids) or used in various industrial procedures.¹ Their formation via the condensation of amines with aldehydes or ketones is a reversible process.¹ In fact, the use of imines as intermediates in multicomponent reactions is very ubiquitous due to the same equilibrium which exists.² Imine-based multicomponent reactions which have gained considerable attention in the past few years include: formation of quinolizidines and indolizidines via A³coupling, other Mannich-type reactions (nitro-Mannich, aza-Friedel-Crafts, Petasis), and the intramolecular aza-Diels-Alder reaction.^{3,4,5} In order to be able to drive the condensation process to completion, the classical method required azeotropic distillation by a Dean-Stark apparatus which obviously necessitated the use of excess amounts of solvents.⁶ Subsequently, alternative eco-friendly procedures were developed including the Schmidt reaction, the oxidative-dehydrogenation of amines and the oxidative coupling of alcohols and amines just to name a few.⁷ Such procedures still may suffer from one or more of the following disadvantages: require expensive metallic catalysts, have a lower atom

economy, require long reaction times, require the use of toxic solvents and show overall low environmental benignity.^{6,7}

After the incorporation of the green chemistry principles into the synthetic chemistry modus operandi, following the works of Anastas and Warner,⁸ the above mentioned syntheses were improved further and rendered more eco-friendly through the use of heterogeneous catalysts such as: sulfated-TiO₂, montmorillonite K-10 clay, sulfated nano-ordered silica and zeolites.⁹⁻¹²

Further recently developed sustainable methodologies have been reported using irradiation techniques.¹³ Moreover the addition of dehydrating agents such as phosphorous-pentoxide-silica have also been shown to drive the reaction to completion by removing the condensation product, ergo water.¹⁴ Obviously such agents require oven drying and reactivation for future re-use.

Another difficulty associated with this synthetic reaction is that in general, ketones are much less reactive when compared with aldehydes rendering ketimine synthesis even more unfavourable and non-green.

In the following research, in continuation of our interest in the application of heterogeneous catalysts,¹⁵ herein we report how various heterogeneous catalysts and some desiccants were tried and compared in terms of activity and efficiency for the imine synthesis reaction. Amberlyst® 15, a cheap commercially available catalyst is found to give the highest yields in short reaction times under neat conditions. In addendum, the unprecedented synthesis of the ketimine from the condensation of cyclohexanamine and cyclohexanone proved successful.

2. Experimental

2.1. Materials used

All commercially available chemicals were purchased from Aldrich and used without further purification.

2.2. Instrumentation

For the characterization of final products and monitoring of the reactions the same procedure described in detail in our previous publications was followed in order to obtain FTIR, NMR and MS and GC spectra.¹⁶

2.3. General procedure

The general procedure for the imine-synthesis reaction involved stirring the aldehyde (5 mmol) and the amine (5.5 mmol) in the presence of 0.2 g of A15 catalyst under neat conditions at room temperature in a nitrogen-dried 25 mL one-neck round bottom flask. The reaction was monitored via both TLCs and/or GC analysis. The catalyst was filtered off by suction and washed appropriately with diethyl ether solvent (approximately 5 – 10 mL). The filtrate was concentrated by rotary evaporation and by a double-stage vacuum oil pump in order to remove the unreacted amine for reactions involving low-boiling amines. The products of aromatic amines were purified by recrystallization from ethanol or by column chromatography using a 9:1, 8:2 or 7:3 hexane/ethyl acetate eluant ratio. The TLC plates used for monitoring were composed of silica

on PET with fluorescent indicator. Plates were observed under a UV lamp at a wavelength of 254 nm before staining in an iodine-saturated chamber. Analytical data for all products are reported in the Supporting Information File.

3. Results and discussion

During the initial screening, the reaction between benzaldehyde (**1a**) and *t*-butylamine (**2a**) was chosen as the model reaction (**Scheme 1**). The latter was always performed at room temperature under quasi-solvent-free conditions in the presence/absence of a number of heterogeneous catalysts and desiccants. In addition, the molar ratios of the reagents and catalyst quantities were also varied. **Table 1** show the results of the preliminary catalyst/drying agent screening trials.

Scheme 1.

Table 1

As evidenced, out of the catalysts and desiccants tried and tested, the best yields were obtained using Montmorillonite K-10, Amberlyst® 15 and acidic alumina. However, the work up of the reactions involving either MK-10 or acidic alumina required the addition of more solvent than that involving Amberlyst® 15 owing to their physical state (powder). Henceforth, Amberlyst® 15 (being in the form of beads) was selected for the subsequent optimization trials especially considering its ease of separation from the reaction mixture. In addition, it was discovered that a smaller amount of Amberlyst® 15 could result in even higher yields (Table 2) possibly owing to easier mechanical stirring and less product adsorption onto the catalyst beads.

Table 2.

One of the main limitations of the condensation of primary amines and aldehydes/ketones is the equilibrium which exists between the products and the substrates. This explains why in the initial trials the amine was used in excess, ergo, to shift the equilibrium forward. Yet, as outlined in **Table 3**, the yields remained practically the same even when the latter mentioned excess was decreased to 0.1 equivalents only.

Table 3.

Subsequently, having identified the ideal conditions (neat, room temperature, 0.2 g per 5 mmol Amberlyst® 15, 0.1 equivalent excess of amine), the substrate scope could be expanded by varying the aldehydes and the amines. In general, the best outcomes were obtained (**Table 4**) when using aromatic aldehydes and aliphatic primary amines due to the higher reactivity of the

aldehydes as opposed to ketones and the greater nucleophilic character of aliphatic amine as opposed to aromatic amines.

Table 4.

Positively, despite their inherent lack of reactivity, aromatic amines also gave appreciable yields as outlined in **Table 5**. Not only, but the primary aliphatic amine, *c*-hexylamine, was able to react successfully with the cyclic ketone, cyclohexanone (**Scheme 2**) to give the product (**3s**) in 85% yield.

Table 5.

Scheme 2

Lastly, the catalyst exhibited good recyclability because the model reaction could be repeated up to 5 times with the same catalyst with the yield decreasing by 10% between the first and last trial (**Figure 1**). The latter decrease is most probably a result of sulfonic acid group inactivation by the reaction with the amine reactant.

Figure 1.

4. Conclusions

The heterogeneous, safe-to-handle, relatively-cheap and commercially-available Amberlyst® 15 was found to be the ideal catalyst for the synthesis of various imines using both aliphatic and aromatic amines and aromatic aldehydes (72 – 99% yields, 17 examples) in significantly short reaction times (2 – 4 hours) at room temperature in neat conditions. The catalyst morphology, i.e. being in the form of microporous beads, enabled it to be easily recovered with minimal solvent use during work up and reused for up to 5 times.

Acknowledgements

The authors would like to thank Prof. Robert M. Borg for assistance with the acquisition of the NMR spectra and Dr. Godwin Sammut for MS analyses.

- a. All reactions were carried out in the presence of 1 mL of diethyl ether on a 5 mmol scale using a 1 : 3 molar ratio of benzaldehyde-1a : amine2a at room temperature (circa 15 – 25 °C). The addition of diethyl ether was required because reaction mixture soon thickened significantly after reaction initiation.
- b. Yield of pure isolated product unless otherwise indicated
- c. No desiccant or catalyst added
- d. Effective pore size in Angstrom
- e. A smaller amount of MK-10 (compared to other catalysts) was used because on addition of larger amounts of MK-10, reaction mixture dried up immediately and the addition of 1 mL of diethyl ether was not enough to aid stirring.
- f. When a larger amount of catalyst was used (1.5 g), the Nafion beads kept moving out of reaction mixture and adhering to reactant flask walls.
- g. Reaction carried out under solventless conditions owing to the small amount of catalyst
- h. Copper iodide leaching was noted due to residual green colour in the crude reaction mixture following catalyst filtration.
