Fibroblast growth factors as tissue repair and regeneration therapeutics

Quentin M Nunes, Yong Li, Changye Sun, Tarja K Kinnunen, David G Fernig

Cell communication is central to the integration of cell function required for the development and homeostasis of multicellular animals. Proteins are an important currency of cell communication, acting locally (auto-, juxta-, or paracrine) or systemically (endocrine). The fibroblast growth factor (FGF) family contributes to the regulation of virtually all aspects of development and organogenesis, and after birth to tissue maintenance, as well as particular aspects of organism physiology. In the West oncology has been the focus of translation of FGF research, whereas in China and to an extent Japan a major focus has been to use FGFs in repair and regeneration settings. These differences have their roots in research history and aims. The Chinese drive into biotechnology and the delivery of engineered clinical grade FGFs by a major Chinese research group were important enablers in this respect. The Chinese language clinical literature is not widely accessible. To put this into context, we provide the essential molecular and functional background to the FGF communication system covering FGF ligands, the heparan sulfate and Klotho co-receptors and FGF receptor (FGFR) tyrosine kinases. We then summarise a selection of case reports that demonstrate the efficacy of engineered recombinant FGF ligands in treating a wide range of conditions that require tissue repair / regeneration. Alongside the functional reasons why application of exogenous FGF ligands does not lead to cancers are described. Together, this highlights that the FGF ligands represent a major opportunity for clinical translation, that has been largely overlooked in the West.
Fibroblast growth factors as tissue repair and regeneration therapeutics

Abstract

Cell communication is central to the integration of cell function required for the development and homeostasis of multicellular animals. Proteins are an important currency of cell communication, acting locally (auto-, juxta-, or paracrine) or systemically (endocrine). The fibroblast growth factor (FGF) family contributes to the regulation of virtually all aspects of development and organogenesis, and after birth to tissue maintenance, as well as particular aspects of organism physiology. In the West oncology has been the focus of translation of FGF research, whereas in China and to an extent Japan a major focus has been to use FGFs in repair and regeneration settings. These differences have their roots in research history and aims. The Chinese drive into biotechnology and the delivery of engineered clinical grade FGFs by a major Chinese research group were important enablers in this respect. The Chinese language clinical literature is not widely accessible. To put this into context, we provide the essential molecular and functional background to the FGF communication system covering FGF ligands, the heparan sulfate and Klotho co-receptors and FGF receptor (FGFR) tyrosine kinases. We then summarise a selection of case reports that demonstrate the efficacy of engineered recombinant FGF ligands in treating a wide range of conditions that require tissue repair / regeneration. Alongside the functional reasons why application of exogenous FGF ligands does not lead to cancers are described. Together, this highlights that the FGF ligands represent a major opportunity for clinical translation that has been largely overlooked in the West.
Overview

In unicellular organisms the unit of natural selection is the cell, whereas in multicellular animals natural selection operates on the organism. This is a very profound difference. The driver is likely to have been simple: there is a limit on the complexity of an individual cell, beyond which it is no longer robust. However, greater organism complexity allows new ecological niches and lifestyles to be exploited. Natural selection has given rise to multicellularity and cell specialisation, as a means to allow a high level of organism complexity in concert with simple and robust cells. This requires a deep functional integration of cells in the organism, achieved through cell communication, which occurs by cells delivering information through the synthesis and secretion of signalling molecules into the extracellular space; these then elicit signals in cells possessing appropriate receptor systems. The entire biochemical landscape, from ions and small molecules to proteins and polysaccharides is used to generate the repertoire of signalling molecules.

In multicellular animals, proteins are common currency in cell communication and are used to transmit information between cells in the organism both locally (intra-, auto-, juxta- and paracrine) and systemically (endocrine). Local transmission of information may be mediated by a soluble, secreted protein, or by a protein anchored in the extracellular matrix or on the plasma membrane of a neighbouring cell. The exploitation of proteins for cell communication by multicellular animals provides access to a very subtle language. This subtlety arises in part from the fact that an individual protein species may have many different isoforms (from splice variants to glycoforms), localisations and interacting partners. Each subset of molecular interactions that an individual protein species can partake in may elicit completely different, sometimes opposing, cellular responses, and, moreover, may change the distance over which communication occurs, e.g., paracrine versus endocrine.

Most therapeutics can be considered to manipulate cell communication, with varying aims, such as reducing overactive communication channels in cancer and inflammatory diseases, or increasing particular channels of communication for tissue repair and regeneration. Clearly, manipulating cell communication therapeutically is not without danger, since the opposite of the desired effect may occur. Less obvious, but an important focus of this review, is that the drivers of scientific discovery can narrow dramatically how a particular communication system is used clinically. This is exemplified by the fibroblast growth factor (FGF) family, which contributes to
the regulation of virtually all aspects of development and organogenesis, and after birth in many
natural processes of tissue repair and the endocrine regulation of particular facets of organism
physiology. In the West, the major focus of clinical translation has been on developing inhibitors
of FGF-mediated cell communication for use in cancer therapy. In the East particularly in China
and to an extent in Japan, a major focus has been to use FGFs in regenerative/repair medical
settings, differences that have their roots in a combination of research history and research aims.
The Chinese clinical literature is not widely accessible and we provide a summary of a number
of published reports to illustrate the breadth and depth of successful clinical applications of FGFs.

The discovery of FGF ligands and their activities
Historically, the growth factor activity was the first to be identified. In hindsight, the paper of
Trowell and Wilmer, which measured the mitogenic activity of saline extracts of different tissues
from the chick can be considered to be the first FGF paper (Trowell & Willmer 1939) – the
activity they isolated from brain would consist of FGF-1, FGF-2 (Burgess & Maciag 1989), as
well as other growth factors active on fibroblasts, e.g., pleiotrophin (Courty et al. 1991), and that
from other tissues largely FGF-2 (Burgess & Maciag 1989; Fernig & Gallagher 1994). Over 30
years later a growth factor activity that stimulated the growth of a fibroblast cell line was
identified in partially purified extracts from bovine pituitary. It was called “fibroblast growth
factor”, simply due to the assay used to measure activity (Rudland et al. 1974). Though an
unsatisfactory name, because FGFs do far more than stimulate fibroblast growth and in a
considerable number of instances they do not even possess this activity, the label has stuck (see
(Burgess & Maciag 1989) for other early names and a brief overview of the discovery of FGF-1
and FGF-2). A great deal of the early work on FGFs, including that of Trowell and Wilmer
(Trowell & Willmer 1939), was from a cancer perspective, driven by the idea that uncontrolled
proliferation is a hallmark of cancers and so growth factors must have a key role to play.
Moreover, the ambition to cure cancers provided funding for this and much subsequent work on
FGFs and other growth factors. This was not misplaced, since the analysis of experimental
tumours and of activities capable of transforming cells in vitro enabled the discovery of some,
but not all of FGFs -3 to -9 (summarised in (Burgess & Maciag 1989; Fernig & Gallagher 1994))
and there are a number of successful FGF receptor (FGFR) inhibitors in oncology (Carter et al.
2015; Turner & Grose 2010).
The interaction with heparin was key to the successful purification of FGF-1 and -2 (Maciag et al. 1984; Shing et al. 1984), and was translated into work on the interaction of these FGFs with the glycosaminoglycan heparan sulfate (HS) in the pericellular and extracellular matrix, e.g., (Vlodavsky et al. 1987). The FGF receptor (FGFR) tyrosine kinases were then identified and soon after, the dependence of the growth factor activity of FGFs on HS (Rapraeger et al. 1991; Yayon et al. 1991) was discovered. This provided a framework within which to understand function, HS controlled the transport of FGFs between cells and was a part of a dual receptor (HS+FGFR) signalling system. Subsequently, some FGFs were found to not bind HS, but to interact with a protein co-receptor, Klotho; these FGFs do not elicit a growth factor response, but instead are endocrine hormones (Belov 2013; Kuro-o et al. 1997; Martin 2012). A further set of FGF proteins, the FGF homology factors or FHFs, are wholly intracellular and do not interact with any of the extracellular receptors and partners of FGFs. As such they are not directly part of the FGF cell communication system and lie outside the scope of this review (for review see (Goldfarb 2005))

**The FGF communication system: molecules and structure**

The core of the FGF communication system comprises a family of ligands, the FGFs, a family of cell surface signal transducing receptors, the FGFRs, and two distinct co-receptors, the Klothos and the glycosaminoglycan heparan sulfate, which is the physiologically relevant polysaccharide; heparin is often used as its experimental proxy, but has important structural differences.

**The FGF ligand family**

Phylogenetic analysis of human protein sequences indicates that there are seven FGF subfamilies: FGF1 and FGF2 (FGF1 subfamily); FGF4, FGF5 and FGF6 (FGF4 subfamily); FGF3, FGF7, FGF10 and FGF22 (FGF7 subfamily); FGF8, FGF17 and FGF18 (FGF8 subfamily); FGF9, FGF16 and FGF20 (FGF9 subfamily); FGF11, FGF12, FGF13 and FGF14 (FGF11 subfamily); FGF19, FGF21, and FGF23 (FGF19 subfamily) (Fig. 1). The members of FGF8, FGF9, FGF11 and FGF19 subfamilies are consistent in the phylogenetic analysis and gene location analysis. However, FGF5 and FGF3 are indicated to be members of FGF4 and FGF7 subfamilies by the analysis of gene location on chromosomes (Horton et al. 2003; Itoh
The phylogenetic relationship based on sequence maps to functional similarities of the FGFs (Ornitz et al. 1996; Xu et al. 2013; Zhang et al. 2006) and it is in this context that FGF subfamilies will be discussed here.

**FGF ligand structure**

FGFs’ molecular weight ranges from 17 to 34 kDa in vertebrates, whereas it reaches to 84 kDa in *Drosophila*. All FGFs share an internal core of similarity with 28 highly conserved, and six invariant amino acid residues (Ornitz 2000). X-ray crystallography of FGFs shows that the FGF family possesses a similar folding pattern to the interleukins IL-1β and IL-1α (Zhu et al. 1991), a β trefoil structure, formed by three sets (Fig 2a) of four β strands connected by loops (Fig. 2b) (Zhang et al. 1991). A variety of studies have demonstrated that the primary heparan sulfate binding site of FGF2 is formed by the strand β1/β2 loop, strands β10 / β11 loop, strand β11 and strands β11 / β12 loop (Fig. 3b) (Baird et al. 1988; Faham et al. 1996; Li et al. 1994; Thompson et al. 1994; Zhang et al. 1991). The receptor binding site involves the strands β8-β9 loop and is distinct from the primary heparan sulfate binding site (Figs 3a, b). This indicates that the binding to receptor and to heparan sulfate are physically separated (Itoh & Ornitz 2004; Ornitz & Itoh 2001; Zhang et al. 1991). Secondary heparan sulfate binding sites are also present in many FGFs and their position on the surface of the ligands may follow their sequence phylogenetic relationship (Ori et al. 2009; Xu et al. 2012) (Figs 3b, c).

**Receptors: Heparan sulfate and FGFR**

*Heparan sulfate* :- Proteoglycans are O-glycosylated proteins, such as perlecan, glypicans and syndecans (Taylor & Gallo 2006; Yung & Chan 2007). The heparan sulfate chains bind and regulate the function of over 435 extracellular proteins, including the paracrine FGFs (Gallagher 2015; Ori et al. 2008; Ori et al. 2011; Xu & Esko 2014). The proteoglycan core proteins are synthesized on the rough endoplasmic reticulum and then transported to the Golgi apparatus where the glycosaminoglycan chains are synthesised (Yanagishita & Hascall 1992). The glycosaminoglycan chains are linear polysaccharides mainly consisting of repeating disaccharide units (Fig. 4a) (Gallagher 2015; Ori et al. 2008; Taylor & Gallo 2006; Xu & Esko 2014). The members of the GAG family are heparan sulfate, chondroitin sulfate (CS), dermatan sulfate (DS), hyaluronan (HA) and keratan sulfate (KS) (Delehedde et al. 2001).
Heparan sulfate is made of repeating disaccharide units of glucuronic acid linked to N-acetylglucosamine (Fig. 4a). In the Golgi apparatus, the synthesis of heparan sulfate chains is started by the assembly of a tetrasaccharide linkage onto a serine residue of the core protein by four enzymes acting sequentially (Xyl transferase, Gal transferase I and II and GalA transferase); the repeat disaccharide units, [4-GlcA β1-4 GlcNacβ1-]n (where n ~25 to 100) are then added by the copolymerases EXT1 and EXT2 (Dreyfuss et al. 2009; Lin 2004; Tumova et al. 2000). After the synthesis of the chain, clusters of N-acetyl glucosamine are removed and N-sulfate groups are added by the dual activity N-deacetylase-N-sulfotransferases (NDSTs) (Dreyfuss et al. 2009; Lin 2004; Tumova et al. 2000). The subsequent modifications on N-sulfated glucosamine containing disaccharides or their neighbours: an epimerase converts glucuronic acid to iduronic acid, which may then be 2-O sulfated and the glucosamine may be 6-O and 3-O sulfated (Dreyfuss et al. 2009; Lin 2004; Tumova et al. 2000).

Since NDSTs selectively act on blocks of disaccharides, the modified heparan sulfate has a domain structure of NA, NAS domain and S domains (Fig. 4b) (Connell & Lortat-Jacob 2013; Dreyfuss et al. 2009; Gallagher 2015; Murphy et al. 2004; Ori et al. 2008). Differences in sulfation level of the NAS and NS domains provide the means for heparan sulfate to bind with varying degrees of selectivity to over 435 proteins (Ori et al. 2008; Xu & Esko 2014), including FGFs binding S-domains and antithrombin III binding transition domains (Turnbull et al. 2001; Xu & Esko 2014). Since the modification reactions by the sulfotransferases do not go to completion, the length and level of sulfation of HS chains are also variable in different cells and extracellular matrices (Dreyfuss et al. 2009; Kirkpatrick & Selleck 2007; Ori et al. 2008; Xu & Esko 2014).

**FGFR**

FGFRs, anchored on the membrane are the key to transferring induced signals into the cell, which direct the target cell activities, such as cell proliferation, differentiation and migration (Beenken & Mohammadi 2009; Ornitz 2000; Turner & Grose 2010). Five different FGFRs (FGFR1-4 and FGFRL1) and many of their alternative spliced isoforms have been found to bind with FGFs and activate a large number of signalling pathways (Itoh & Ornitz 2011a; Powers et al. 2000; Wiedemann & Trueb 2000). FGFR1-4 possess three extracellular immunoglobulin-like
loops, I, II and III (often termed D1, D2 and D3), a transmembrane linker and a cytoplasmic kinase domain (Beenken & Mohammadi 2009; Goetz & Mohammadi 2013; Powers et al. 2000). FGFRL1 differs in that its intracellular domain lacks a tyrosine kinase (Kim et al. 2001; Sleeman et al. 2001; Wiedemann & Trueb 2000). Half of D3 is encoded in FGFR1, FGFR2 and FGFR3 by alternative exons. This gives rise to the ‘b’ and ‘c’ isoforms of the transmembrane receptor, which impart additional ligand selectivity (Ornitz et al. 1996; Zhang et al. 2006). In addition, the tyrosine kinase FGFRs also bind heparan sulfate (Kan et al. 1993; Powell et al. 2002), which leads to one ternary FGF-FGFR-HS signalling structure (Schlessinger et al. 2000b).

The FGFRs have varying degrees of selectivity for different FGFs, and the selectivity is most conserved between FGFs in same subfamily (Ornitz et al. 1996; Xu et al. 2012; Xu et al. 2013; Zhang et al. 2006). FGF1 was recognised as a universal ligand for all the FGFRs, while FGF2 and members of the FGF4 subfamily prefer to interact with FGFR 1c (Zhang et al. 2006). For the ‘c’ isoform, the preference is FGFR1c > FGFR 2c and FGFR 3c, though the FGF4 subfamily is clearly distinguished from FGF1 subfamily in terms of their selectivity for FGFR 1b, which they do not bind, in contrast to FGF1 and FGF2 (Ornitz et al. 1996; Zhang et al. 2006). Members of the FGF8 and FGF9 subfamilies preferentially bind to FGFR 3c (FGFR 3c > FGFR 2c and 1c), while members of FGF7 subfamily mainly bind FGFR 2b and 1b (Ornitz et al. 1996; Zhang et al. 2006).

**Klotho co-receptors**

Klotho co-receptors (alpha and beta-Klotho/KLB) are type 1 transmembrane proteins that define tissue specific activities of circulating endocrine FGFs (for reviews see (Belov 2013; Kuro-o 2012; Martin 2012). *aKlotho* was originally identified as an aging suppressor gene (Kuro-o et al. 1997). Findings that mice with disrupted *aKlotho* expression display identical phenotypes to mice deficient in FGF23 including shortened life span, growth retardation, muscle atrophy, vascular calcification in the kidneys and disrupted serum phosphate balance led to the discovery of αKlotho as an obligatory co-receptor for FGF23 to bind and activate FGFR in the kidney (Kurosu et al. 2006; Urakawa et al. 2006). Bone derived FGF23 acts in the *aKlotho* expressing kidney to regulate vitamin D and phosphate homeostasis. Beta-Klotho (KLB) was identified by its sequence homology to αKlotho (Ito et al. 2000), and later identified as a co-receptor to allow FGF19 and -21 to bind and signal via their canonical FGFRs in bile acid, glucose and lipid
metabolism, respectively (Kharitonkov et al. 2008; Kurosu et al. 2007; Lin 2007; Wu 2007).

The ectodomains of Klotho co-receptors are composed of two KL domains with sequence homology to beta-glucosidases (Ito et al. 2000; Kuro-o et al. 1997). αKlotho also exists in a secreted form, either via alternative splicing or via shedding of the ectodomain by matrix metalloproteases. The secreted form of Klotho has been shown to modulate glycans on Transient Receptor Potential calcium channels TRPV5 and TRPV6 (Chang et al. 2005) and renal outer medullary potassium channels (ROMK1) (Cha et al. 2009) in vitro, increasing their cell-surface retention.

**Assembly of signalling complexes**

The binding of the FGF ligand to its receptor with/without HS (co-receptor) causes the FGFR to dimerise. This in return enables phosphorylation of tyrosine residues in the kinase activation loop and then of tyrosine that are docking sites for signalling proteins (Goetz & Mohammadi 2013). The latter activate many intracellular signalling pathways, e.g. RAS-RAF-MAPK and PI3K-AKT, which regulate cell fate and specific cell activities (Dorey & Amaya 2010; Turner & Grose 2010). Previous studies suggest HS/heparin is required for many, but not all signalling (Izvolsky et al. 2003). FGF signalling can be negatively regulated by internalisation and degradation, as well as by transmembrane regulators, such as FGFRL1 and intracellular ones, e.g. Sprouty and Spry (Casci et al. 1999; Hacohen et al. 1998) and MAPK phosphatase 3 (Turner & Grose 2010).

Since there is a great diversity of FGF ligands, FGFR isoforms and HS structure and feedback loops, the understanding of FGF signalling is still far from complete (Dorey & Amaya 2010).

**Alternative partners**

FGFs and FGFR interact directly with a large number of other partners, both extracellularly and, following the internalisation of ligand-receptor complexes, intracellularly. In some instances, e.g., FGF-2 binding integrins (Rusnati et al. 1997), these may be additional to the core complex of FGF, FGFR and HS, but in other cases, e.g., cadherins, these are orthogonal partners of one component of the core FGF communication system, the FGFR (Doherty & Walsh 1996). A partial list of the alternative extracellular partners has been reviewed in (Polanska et al. 2009b). The intracellular partners and functions of FGF receptor-ligand complex components
translocated to the nucleocytoplasmic space have also been recently reviewed (Coleman et al. 2014).

**Diversification and switching of function: hints from *C. elegans***

*C. elegans* possesses one of the simplest FGF communication systems, comprising two ligands, EGL-17 (Burdine et al. 1997) and LET-756 (Roubin et al. 1999), a single FGFR, EGL-15 (DeVore et al. 1995), and two orthologues of Klotho, KLO-1 and KLO-2 (Polanska et al. 2011). The EGL-15 receptor is alternatively spliced into an “A” and a “B” isoform, resulting in structural differences in the extracellular domain of the receptor between immunoglobulin domains I and II (Goodman et al. 2003). The major functions of EGL-15 are in the cell migration of sex myoblasts (DeVore et al. 1995) neural development (Bulow et al. 2004; Fleming et al. 2005) and an early essential function (DeVore et al. 1995) associated with physiological homeostasis (Huang & Stern 2004; Polanska et al. 2009a; Polanska et al. 2011). EGL-17/FGF acts as a chemoattractant to guide sex myoblasts (Burdine et al. 1998), whereas LET-756/FGF is required for the essential function of EGL-15, as animals lacking LET-756 arrest at early larval stage (Roubin et al. 1999). In mammals, the “IIIb” and “IIIc” isoforms of FGFRs enable ligand selectivity. In *C. elegans* this ligand to receptor pairing is determined in part by tissue specific expression of the ligand and the “A” and “B” receptor isoforms (Goodman et al. 2003; Lo et al. 2008). *egl-15*(5B) is predominantly expressed in the hypodermis (Lo et al. 2008), where it mediates fluid homeostasis (Huang & Stern 2004), whereas *egl-15*(5A) isoform is expressed in the M lineage, which gives rise to the sex myoblasts. Heterologous expression of *egl-17* driven by let-756 promoter can stimulate EGL-15(5B) and partially rescue the larval arrest phenotype of mutants lacking LET-756 and expression of *let-756* driven by *egl-17* promoter can partially rescue sex myoblast migration in EGL-15-deficient worms (Goodman et al. 2003). However, although expression of either isoform of *egl-15* in the hypodermis can mediate the fluid homeostasis phenotype, only EGL-15(5A) isoform can mediate sex myoblast chemoattraction (Lo et al. 2008). Thus, the functional specificity of EGL-15 is determined by the extracellular receptor isoform and the availability of the ligand. That there are no multicellular organisms possessing just a single FGF ligand and one FGFR isoform may reflect the importance of selective communication between tissue compartments and of the ability of cells to switch the
ligand channel they are tuned to during development, without changing the receiver (the receptor
kinase and downstream signalling).

The role of EGL-15 in the regulation of *C. elegans* fluid homeostasis was first discovered in
mutants of a phosphatase, which acts downstream of EGL-15 (Kokel et al. 1998). This
phosphatase, CLR-1, acts as a negative regulator of EGL-15, and its absence leads to excess
EGL-15 activity and accumulation of fluid within the *C. elegans* pseudocoelom and a clear (clr)
phenotype. Excess EGL-15 activity and clear phenotype can also be achieved by mutation of *N-
glycosylation sites in the extracellular domain of the EGL-15 receptor* (Polanska et al. 2009a) as
*N*-glycans act as a brake on receptor activation (Duchesne et al. 2006). Under laboratory
conditions *C. elegans* must actively excrete fluid. The major organs responsible for fluid balance
are the hypodermis, which expresses *egl-15(5B)* and *klo-2* (Polanska et al. 2011) and the
excretory canal, which is equivalent to the mammalian kidney and expresses *klo-1* (Polanska et
al. 2011). Complete loss of function of EGL-15 or LET-756 leads to loss of *klo-1* expression and
lack of functional excretory canals (Polanska et al. 2011), a likely explanation of the early larval
lethality of the mutants defective of LET-756/EGL-15 signalling.

Thus, in *C. elegans* the same FGFs act as growth factors, morphogens and hormones, whereas in
mammals different FGFs perform the local and systemic functions. EGL-15 associates with
Klotho co-receptors to mediate the fluid homeostasis function (Polanska et al. 2011), which is
totally analogous to the mode of action of endocrine FGFs in mammals. Although there is
currently no genetic evidence to suggest that, as in mammals, the assembly of a signalling
complex of the *C. elegans* FGF ligands with EGL-15 and subsequent receptor activation would
depend on the heparan sulfate co-receptor *in vivo*, biochemical evidence shows that EGL-
15/FGFR binds to heparin, a proxy for HS (Polanska et al. 2011), whereas sequence alignment of
EGF-17 and LET-756 to mammalian FGFs indicates that they possess HS binding sites (Xu et al.
2012). Importantly, binding to HS would not preclude a hormone homeostatic activity of *C
elegans* FGFs, since the range of the FGF would be significant compared to the animal’s body
size; *C. elegans* is small, (adult hermaphrodites ~1 mm). Thus, a reasonable hypothesis is that
the communication system used in development, LET-756 and EGL-15 is then co-opted into
endocrine homeostasis. As animals grew larger, this would not longer be possible.

Diversification of the FGF family and weakening of heparan sulfate binding would then allow
both the growth factor/morphogen activity, which is local due to heparan sulfate binding and the
systemic hormonal activity to be retained. In support of this idea is the demonstration that a human FGF-1 with its primary heparan sulfate binding site mutated is reprogrammed from a growth factor to a FGF-21 like hormone, controlling metabolism (Suh et al. 2014).

The aspects of FGF activities linked to cancers

As noted above, a great deal of the early work on FGFs was from a cancer perspective, though there was also a considerable effort directed at regeneration of damaged tissues. While there is a bias in the scientific literature against reporting negative results, there are some reports that showed in animal models and in clinical samples that there was not a simple relationship between FGF ligand expression and tumour formation and progression. Thus, when FGF-2 mRNA levels were analysed in a cohort of breast cancer patients, elevated expression of FGF-2 mRNA correlated with a good prognostic outcome, the opposite of the result expected from the naïve perspective that “FGF2 = uncontrolled growth + angiogenesis = cancer” (Anandappa et al. 1993). Similarly, in a syngeneic rat model of breast cancer, overexpression of FGF2 failed to produce any metastases (Davies et al. 1996). Given the difficulty in publishing negative results, there is likely a very large body of work that demonstrates the absence of a direct association between the expression of FGF ligands and cancer.

One reason is that, at least for FGF-1 and FGF-2, the ligand is often not limiting. That is, there is a lot of ligand stored on heparan sulfate in tissues, which is then accessed during repair. The discovery of the storage of FGF2 on heparan sulfate of extracellular matrix (Vlodavsky et al. 1987) was followed by the realisation that stored FGF2 could elicit a response at least in cultured cells (REFS Presta), by diffusion within matrix (Duchesne et al. 2012). The expression of other FGF ligands is, in contrast, often induced. However, like FGF1 and FGF2, their activity is restricted, again through binding to heparan sulfate and due to their selectivity for FGFRs. An important facet of development and endogenous tissue repair is the mobilisation of FGF ligands by heparanase, a beta glucuronidase, which cleaves heparan sulfate in NA and NAS domains, liberating growth factor bound to an S domain (Arvatz et al. 2011; Barash et al. 2010; Kato et al. 1998; Patel et al. ; Ramani et al. 2013). This plays a key role in many cancers (Arvatz et al. 2011; Barash et al. 2010; Ramani et al. 2013). Thus, the mechanistic link between the FGF communication system and cancers is on the side of the mobilisation of FGFs from such stores (particularly by heparanase, though proteases are likely to also have a role) and of increases in
the activity of FGFRs (Carter et al. 2015; Turner & Grose 2010). Thus, in contrast to their ligands, the FGFRs are established drivers of tumour progression. This arises from: activating mutations; isoform switching, e.g., between the classic epithelial, FGFR2-IIIb isoform that binds FGF-7 family members and FGFR2-IIIc isoform, that binds epithelial synthesized and mesenchymally stored FGFs, including FGF-2 (Carter et al. 2015; Turner & Grose 2010).

**FGFs as repair factors**

The use of FGFs to repair damaged tissue is a long-standing research area, however, until recently in the West it was entirely confined to model systems. In Japan, alongside the cancer research track, a repair track leading to clinical applications was developed. In contrast, in China FGF research was from the late 1980s spearheaded by the drive to develop a biotechnology industry. This resulted in successful engineered production of FGF1 and FGF2, e.g., (Wu et al. 2005; Wu et al. 2004; Yao et al. 2006; Zhao et al. 2004) and a substantial effort in experimental medicine, including pharmacokinetic and toxicity studies, e.g., (Li et al. 2002; Xu et al. 2003) to develop clinical applications. In much of this work the original nomenclature, aFGF and bFGF is used for FGF1 and FGF2, respectively; in the following summary of some of the clinical studies the currently accepted numerical nomenclature is employed. A major clinical focus in China has been the use of FGF2 as a repair/regeneration factor in conditions as diverse as burns, chronic wounds, oral ulcers, vascular ulcers, diabetic ulcers, pressure ulcers and surgical incisions. As the Chinese studies are not generally accessible, we have summarised a number of these below, alongside other work on the same conditions.

**Clinical applications of FGF2**

**Burns**

Liu XH et al. (Liu et al. 2005) investigated the use of FGF2 in the treatment of burns and chronic wounds. Patients were divided into a burn wound group (n=62), a donor site wound group (n=36) and a chronic wound group (n=65). The burn wounds included superficial partial thickness burns and deep partial thickness burns; chronic wounds included wounds that did not heal following routine treatment for 4 weeks, residual granulation wounds, pressure ulcers, sinuses, and diabetic ulcers. The burn wound group was treated with FGF2 in addition to the standard treatment. Self-control randomization was applied to the burn wound group and donor
site wound group with comparisons of the same subject before and after treatment. The control group was treated with equal amounts of saline in addition to the standard treatment. The results showed that FGF2 significantly shortened the time to complete wound healing in the three wound groups compared to the control group.

Guo XH et al. (Guo 2006) randomly assigned 80 cases of deep partial thickness burn wounds to a treatment group and a control group. In the treatment group, a gauze pad impregnated with FGF2 solution was applied to the debrided wound, which was then covered with another gauze pad containing 1% (w/w) silver sulfadiazine. Apart from substituting normal saline for FGF2 the control group was subjected to the same treatment as the FGF2 group. The results showed that the average healing time for superficial partial thickness burn wounds in the FGF2-treated group was significantly shorter as compared to the control group (9.51 ± 1.86 days vs. 12.43 ± 2.03 days, $p < 0.05$). Similarly, the healing time in the deep partial thickness burn wounds in the FGF2 treatment group was significantly shorter than the control group (18.36 ± 4.87 days vs. 22.35 ± 5.60 days, $p < 0.01$).

FGF2 has also been shown to accelerate healing and improves scar quality in second-degree burns (Akita et al. 2008). Since the speed of wound healing is an important factor influencing the outcome of treatment, as well as a crucial step in burn wound treatment and the quality of wound healing has a direct bearing on the quality of life of patients, FGF2 clearly has clinical efficacy in a variety of burn settings.

**Surgical wounds**

**Surgical incisions:** Surgical incisions leave scars as part of the normal healing process. These scars vary from being narrow, wide, atrophied or hypertrophic and sometimes cause medical problems, or social ones because of their cosmetic appearance (Rockwell et al. 1989). A study by Ono et al. (Ono et al. 2007) examined the effect of local administration of FGF2 on sutured wounds. FGF2 was injected into the dermis of the wound margins using a needle immediately after the skin was sutured following an operation. None of the patients treated with FGF2 had hypertrophic scars compared to the control group and scarring was significantly lower in the groups treated with FGF2, as compared to the control group.
Skin graft wounds:— Healing of the donor site wounds, created after skin graft harvesting, involves the regeneration of epithelial cells in the residual skin appendages (Metcalf & Ferguson 2007). Early healing of donor site wounds helps to reduce trauma and body consumption, thereby facilitating the treatment of the primary disease.

Xu et al. (Xu et al. 2000) conducted a clinical study to examine the efficacy of topical application of FGF2 on 48 donor site wounds in 34 patients, which were created by harvesting intermediate split thickness skin grafts. The wounds before treatment served as self-controls. Following the harvesting of the skin grafts, the wound surface was evenly coated with FGF2 using a cotton swab, covered with vaseline gauze, and dressed. The control wounds were smeared only with the vehicle without the FGF2, the rest of the topical treatment procedures being identical as the treatment group. The results showed healing time in wounds treated with FGF2 was 2.8 days shorter compared to control wounds ($p < 0.01$). Moreover, FGF2-treated wounds appeared flatter, smoother and firmer and were difficult to tear off, as compared to the control wounds. The use of FGF2 yielded no adverse reactions.

Full thickness skin grafts in avulsion injuries:— Matsumine et al. (Matsumine 2015) described the topical use of FGF2 in the treatment of avulsion wounds with full thickness grafts using the avulsed skin. The contaminated subcutaneous fat tissue on the inside of skin was excised and the avulsed skin was processed into a full-thickness skin graft. Drainage holes (5-10 mm in diameter) were made on the graft to prevent seroma and haematoma formation. FGF2 was sprayed onto the graft bed, followed by application of the graft. Skin grafts that did not take were scraped away, preserving the revascularized viable dermis where possible. FGF2 was then sprayed again onto this surface to promote epithelialization. Wound closure was achieved in all cases with conservative therapy. This procedure promoted wound healing with the formation of good-quality, flexible scars and prevented postoperative ulcer formation and scar contracture.

Cosmetic surgical incisions:— Wound healing quality is important in the success of cosmetic surgery. Lu et al. (Lu et al. 2009) examined the effects of FGF2 on wound repair in 60 female patients who underwent cosmetic surgery. All surgical incisions were clean cuts, and self-controls were used. In the treatment group FGF2 was applied once daily until removal of stitches, starting with the first postoperative day. Wounds due to laser resurfacing were smeared with...
FGF2 twice daily until natural decrustation occurred. The control group was subjected to conventional dressing change until removal of stitches. The results showed that in the FGF2 group whose wounds resulted from laser resurfacing, the average decrustation time was significantly shorter than in the control group (6.2 days vs. 8.1 days, p < 0.05). The FGF2-treated groups showed good healing. In addition, exudate and swelling post surgery were milder in the FGF2 groups than in the control group. There were no adverse reactions in the FGF2 groups. Quality of wound healing was superior and the healing time was shorter in the FGF2 groups as compared to the control group, indicating that FGF2 has a favourable effect on cosmetic surgical incision healing.

Obstetric wounds:- Dehiscence of caesarean section incisions may occur in the form of a superficial dehiscence, in which the skin and subcutaneous fat layer break open, most often due to fat liquefaction caused by subcutaneous fat hypertrophy in pregnant women. In addition, a long trial of labour, excessive vaginal examinations, vaginitis, and intrauterine infections may potentially lead to an increase in infected incisions. Anaemia, hypoproteinemia, malnutrition, and diabetes in the perinatal period can result in poor healing capacities of local tissues. These factors can adversely affect wound healing extending hospital stay, and increasing costs. Chen et al. (Chen & He 2004) randomly assigned 60 patients with wound dehiscence following a caesarian section to two groups: an observation group and a control group. After debridement of the wounds, FGF2 was sprayed on the wounds and they were sutured the next day. Wound dressings were changed regularly. The control group was treated similarly, but without the use of FGF2 spray. The results showed that there was no difference in the healing time of patients with dehiscence measuring 5 cm or above in the observation group as compared to the control group (7.6 ± 1.0 days vs. to 7.4 +/- 0.8, p > 0.05). However, the healing time in patients with dehiscence measuring 5 cm or below was significantly shorter than the control group (6.8 ± 1.5 days vs. 11.2 ± 1.2, p < 0.01).

Orthopaedic trauma wounds:- FGF signalling plays an important role in skeletal development (Su et al. 2008). Tissue necrosis and infection of fresh skin defect wounds, grafted flaps, and skin grafts occurs following orthopaedic trauma surgery. In order to shorten the healing time and
reduce the rate of skin re-grafting, FGF2 has been directly applied to fresh and debrided necrotic
wounds.

Zang et al. (Zang et al. 2005) investigated the use of a FGF2 biological protein sponge for
traumatic ulcers. Sterile FGF2 biological protein sponge was applied to traumatic skin ulcers in
20 patients. The results showed that the wound-healing rate within 3 weeks was 95% in the FGF
group and 55% in the control group, and that the rate of skin re-grafting in the FGF2 group was
significantly lower than that in the control group. Wound secretions and peri-wound
inflammation were markedly less severe in the FGF2 group as compared to the control group. No
obvious adverse reactions were reported in either group. These data indicate that FGF2
biological protein sponge may promote the healing of traumatic ulcers and shorten healing time.

Oral Diseases:- Oral ulcers are a common disease of the oral mucosa and tend to recur.
Pathologically, ulcers of oral mucosa are mainly characterized by dissolution, rupture, and
shedding of local oral mucosal epithelium to form non-specific ulcers.

A study by Jiang et al. (Jiang et al. 2013) investigated the use of topical application of
diosmectite (DS) and FGF2 paste in the treatment of minor recurrent aphthous stomatitis. Four
pastes, containing FGF2 and DS, DS alone, FGF2 alone, and vehicle only, were used in 129
participants. DS-FGF2 significantly lowered ulcer pain scores ($p < 0.05$ for days 3, 4, 5, and 6)
as compared to the other pastes. Ulcer size was significantly reduced ($p < 0.05$ for days 2, 4, and
6) in this group. No obvious adverse drug effects were observed.

Radiotherapy is commonly used to treat head and neck cancer. However, when the radiation dose
rises to about 20 Gy - 30 Gy, acute inflammation of the oral mucosa usually occurs, the
symptoms of which include, among other things, oropharyngeal pain, and oral ulcers associated
with oedema or pseudomembrane formation. Food intake is affected as a result. Moreover, the
severity of the symptoms increases with the radiation dose. Patients who experience serious
symptoms have to suspend the treatment, and the final efficacy of the treatment is thus impaired.

Huang et al. (Huang et al. 2009) used FGF2 in 20 patients who had stomatitis as a result of
radiation therapy for head and neck cancer. The treatment group was treated with FGF2 whereas
the control group was treated with alternate mouthwash (0.9% (w/v) sodium chloride and 2.5%
(w/v) sodium bicarbonate solution). The results showed that FGF2 significantly reduced the
incidence of radiation stomatitis and shortened the healing time of stomatitis. No local or systemic adverse reactions were noted.

Ren et al. (Ren & Shun 2002) conducted a double-blind study, in which 121 patients with mild aphthous ulcers were randomly assigned to either FGF2 group (n=63) or control group (n=58). In the FGF2 group, FGF2 was locally sprayed onto the surface of ulcers; in the control group, 0.2% (w/v) chlorhexidine solution was sprayed on the ulcers. The results showed that the effective rate at day 3 was 90.48% in the FGF2 group and 60.34% in the control group (p < 0.05). Meanwhile, the average healing time of ulcers was significantly shorter in the FGF2 group than in the control group. The results show that FGF2 exhibits significant efficacy for mild recurrent aphthous oral ulcers.

Tympanic membrane perforations:- While most traumatic perforations of the tympanic membrane tend to heal spontaneously, large perforations may often fail to do so. The management of these is still open to debate, with a number of specialists recommending an early myringoplasty to improve outcomes (Conoyer et al. 2007). Lou and Wang (Lou & Wang 2013) undertook a prospective, sequential allocation, three-armed, controlled clinical study to compare perforation edge approximation vs. FGF2 application in the management of traumatic perforations of the tympanic membrane. Patients were divided into 3 groups: no intervention (n=18), edge approximation (n=20) and direct application of FGF2 (n=20). Otoscopy was performed before and after treatment and response measurements were made, such as closure rate, closure time and rate of otorrhoea. Perforation closure was significantly higher in the FGF2 group (100%) as compared to the edge approximation (60%) and control (56%) groups (p<0.05). Average closure time was significantly shorter in the FGF2 treatment group (12.4 +/- 3.6 days) as compared to the edge approximation (46.3 +/- 8.7 days) and control (48.2 +/- 5.3 days) groups (p<0.05). Lou et al. (Lou et al. 2014) showed that a lower dose of FGF2 (0.1 to 0.15 mL) was more effective than a higher dose (0.25 to 0.3 mL). Hakuba et al. (Hakuba et al. 2010) demonstrated that FGF2 combined with atelocollagen was an effective treatment for chronic tympanic membrane perforations.

Pressure Ulcers:- Treatment of pressure ulcers is a major problem for clinical care. Pressure ulcers can increase patients’ suffering, extend the duration of illness, and, when serious, may
even prove to be life threatening due to sepsis resulted from secondary infection. Commonly used treatments over the years have included innovative mattresses, ointments, creams, solutions, dressings, ultrasonography, ultraviolet heat lamps, and surgery.

Robson et al. (Robson et al. 1992) investigated the role of FGF2 in the treatment of pressure ulcers with a randomized, blinded, placebo-controlled trial, which enrolled 50 patients with pressure ulcers varying in size from 10 to 200 cm$^3$. The results showed that compared with placebo-treated patients, the number of FGF2-treated patients whose ulcers shrank by 70%, increased significantly (60/100 vs. 29/100, $p = 0.047$). Histological analysis of FGF2-treated wounds showed a significant increase in the number of fibroblasts and capillaries.

Diabetic foot: Diabetic foot is a serious complication of diabetes and an important cause of diabetes-related disability. When diabetic foot develops, the patient's feet are prone to injury, infection, ulcers and gangrene.

Uchi et al. (Uchi et al. 2009) conducted a randomized, double blind, dose-ranging, placebo-controlled trial to examine the clinical efficacy of FGF2 in the treatment of diabetic ulcer. Patients’ diabetic ulcers were randomized into a placebo group ($n = 51$), a 0.001% (w/v) FGF2 treatment group ($n = 49$) and a 0.01% (w/v) FGF2 treatment group ($n = 50$), with the primary outcome being the percentage of patients showing a 75% or greater reduction in the area of ulcer. The area of ulcer decreased by 75% or more in 57.5% (27/47), 72.3% (34/47), and 82.2% (37/45) in the placebo, 0.001% (w/v) FGF2 and 0.01% (w/v) FGF2 groups, with significant differences between the 0.01% (w/v) FGF2 treatment and placebo groups ($p = 0.025$). Cure rates were 46.8%, 57.4%, and 66.7% in the placebo, 0.001% (w/v) FGF and 0.01% (w/v) FGF2 groups. This trial showed that FGF2 accelerates healing of diabetic ulcers.

Other applications: Repair of cerebrospinal fluid leakage is difficult, which is especially so when a large fistula, with concomitant mucosal damage and infection, has developed from repeated transsphenoidal operations. Kubo et al. (Kubo et al. 2005) reported a 27-year-old woman with intractable cerebrospinal fluid rhinorrhea who had undergone repeated operations for a relapsing Rathke's cleft cyst. They repaired the sellar floor defect using mucosal flaps via an endonasal endoscopic approach and occluded the fistula by applying FGF2 to the area to promote granulation. FGF2 was repeatedly applied endoscopically to the mucosal flaps, which
turned into granulation-like tissue, and complete mucosal covering was attained. This method of
treating the intractable fistula with mucosal flaps and FGF2 may present a new clinical
application of FGF2 and should be examined in a large number of patients in the future.
The mucosa of the vocal folds atrophies with age causing glottal insufficiency, which is difficult
to treat. Hirano et al. (Hirano et al. 2008) reported a case of a patient, with atrophied vocal folds,
who was treated with FGF2 injections into the folds under local anaesthesia. The atrophy of the
vocal fold improved within a week following the injection and the glottic gap disappeared.
Aerodynamic and acoustic parameters also showed remarkable improvement, when measured.
Subsequently, a trial (Hirano et al. 2012) demonstrated that this treatment might be safe and
effective in the treatment of age-related vocal fold atrophy.

Prospects

In Europe and N America the substantial investment by cancer sources into growth factors such
as the FGFs has resulted in oncology directed clinical translation, in the form of FGFR inhibitors
(Carter et al. 2015; Turner & Grose 2010). In contrast the biotechnology drive in China resulted
in exploitation of engineered FGF ligands to repair and regenerate damaged tissue in a wide
range of settings, with Japan having clinical experience in both areas. We have not been able to
identify reports of adverse reactions to treatment with FGF ligands – these undoubtedly occur,
but the frequency or their severity may be too low and confounded by the underlying medical
condition, such that they have not appeared in the case literature. In any event, it is clear that the
Chinese and Japanese experience with FGF ligands as biologics in repair and regeneration
clinical scenarios has been an outstanding success; FGFs in China have progressed from
engineered biotechnology products (Wu et al. 2005; Wu et al. 2004; Yao et al. 2006; Zhao et al.
2004) to the Chinese Pharmacopeia (Pharmacopeia 2015). Many of the conditions, e.g., diabetic
foot, make important and growing demands on healthcare systems and carry considerable
socioeconomic costs. Thus, Western medical practice may usefully follow where China has led
and explore the use of FGF ligands as repair and regeneration agents. The realisation of the
clinical potential of the FGF communication system outside of oncology has been long overdue
on the West. However, with industry now actively engaged in, for example, developed of FGF21
based therapeutics for metabolic syndrome (Kharitonenkov & Shanafelt 2008; Kharitonenkov &
Shanafelt 2009; Zhang & Li 2014) and of FGF18 in osteoarthritis (Carli et al. 2012; Mori et al. 2014) it is likely that we will see FGF biologics in clinical use in the West, as well as in the East.

Wu X, Li X, Su Z, Zheng Q, and Wu S. 2005. For improving the condition of bFGF, which is unstable, short half-life and immunoreaction, the bFGF mutant has been designed to replace Cys-25/69/92 with serine residues. The bFGF mutant has been shown that the mutant could induce the Balb/c cell proliferation as same level as wild-type. *China Biotechnology* 25:32-35.

Wu X, Su Z, Zheng Q, Huang Y, Ya D, and Li X. 2004. For increasing the yield of aFGF, the truncated aFGF (shaFGF), which has been eliminated the First 19 amino acids at N-terminal, had been produced up to 25% of total cellular protein in E.coli. Both ShaFGF and wild-type aFGF (haFGF) have been shown to have similar level of mitogenic activity by using MTT method. *Journal of China Pharmaceutical University* 35:470-473.

Zhao J, Fu X, Chen W, Sun T, Zhen S, Weng L, and Zhang Y. 2004. The wild-type aFGF has been shown to significantly induce the cutaneous cell proliferation, whereas the truncated aFGF, which had been truncated the N-terminal sequence “21NYKKPKL27”, had no apparent impact on cell proliferation, which may reduce the effect of aFGF on the induction of tumour. *Chin Crit Care Med* 16:458-459.

Figure 1 (on next page)

Phylogenetic relationship of the FGFs based on amino acid sequence

According to amino acid sequence, Dendroscope was used to show that FGF family is divided into seven subfamilies. The branch lengths relates directly to the evolutionary relationship of FGFs.

FGF interactions with FGFR and heparin/heparan sulfate

**(A):** Ternary structure of FGF-FGFR-heparin complex (1FQ9 (Schlessinger et al. 2000a)). FGFs interact with the D2 and D3 domain and the linker between these two domains. A heparin octasaccharide binds to the conserved canonical binding site on FGFs, which is opposite to the N-terminal, and to the basic canyon in the FGFR. **(B):** Heparin binding sites of FGF2 (1FQ9) identified by a selective labelling approach (Ori et al. 2009). Three binding sites were recognised: the canonical binding site (HBS1), and two secondary and relatively weaker binding sites (HBS2 and HBS3). **(C):** Heparin binding site of FGF9 (1G82 (Hecht et al. 2001)). Only the conserved HBS1 was identified, indicating that FGF9 does not possess secondary polysaccharide binding sites (Xu et al. 2012), subsequently confirmed in biophysical experiments (Migliorini et al. 2015). Green indicates the N-terminal of the proteins. Grey is FGFR1. Magenta are FGFs (FGF2 in B and FGF9 in C). The residues in blue are the heparin binding sites of the FGFs.
Figure 4 (on next page)

Structures of disaccharide units of HS and heparin

(A): Structure of disaccharide unit of heparin/HS. Top: the glucuronic acid containing disaccharide. This is generally not or only slightly modified by sulfation (in red). Bottom: the iduronic acid containing disaccharide, which always contains an N-sulfated glucosamine (red) and is often further modified by O-sulfation (red). (B): Structure of HS chains. The polysaccharide chain is covalently linked to a serine on the proteoglycan core protein. The sulfate groups are added by sulphotransferases after the GAG chain is polymerised. Due to the hierarchical dependence of the post polymerisation reactions and the sulfation of discrete blocks of N-acetylglicosamines by N-deacetylase-N-sulfotransferases (NDSTs), the HS chain has a domain structure of alternating NA (GlcA/GlcNAc), NAS (~ one disaccharide in two is N-sulfated) and S (every glucosamine is N-sulfated) domains. Chain lengths vary from ~25 disaccharides to over 100. Heparin, a common experimental proxy for heparan sulfate is ~30 disaccharides in length and can be considered to be a highly sulfated NS domain.
