A tide prediction and tide height control system for laboratory mesocosms

Luke P Miller, Jeremy D Long

Experimental mesocosm studies of rocky shore and estuarine intertidal systems may benefit from the application of natural tide cycles to better replicate variation in immersion time, water depth, and attendant fluctuations in abiotic and edaphic conditions. Here we describe a stand-alone microcontroller tide prediction open-source software program, coupled with a mechanical tidal elevation control system, which allows continuous adjustment of aquarium water depths in synchrony with local tide cycles. We used this system to monitor the growth of *Spartina foliosa* marsh cordgrass and scale insect herbivores at three simulated shore elevations in laboratory mesocosms. Plant growth decreased with increasing shore elevation, while scale insect population growth on the plants was not strongly affected by immersion time. This system shows promise for a range of laboratory mesocosm studies where natural tide cycling could impact organism performance or behavior, while the tide prediction system could additionally be utilized in field experiments where treatments need to be applied at certain stages of the tide cycle.

14 **Abstract**

15 Experimental mesocosm studies of rocky shore and estuarine intertidal systems may benefit
16 from the application of natural tide cycles to better replicate variation in immersion time,
17 water depth, and attendant fluctuations in abiotic and edaphic conditions. Here we describe a
18 stand-alone microcontroller tide prediction open-source software program, coupled with a
19 mechanical tidal elevation control system, which allows continuous adjustment of aquarium
20 water depths in synchrony with local tide cycles. We used this system to monitor the growth
21 of *Spartina foliosa* marsh cordgrass and scale insect herbivores at three simulated shore
22 elevations in laboratory mesocosms. Plant growth decreased with increasing shore elevation,
23 while scale insect population growth on the plants was not strongly affected by immersion
24 time. This system shows promise for a range of laboratory mesocosm studies where natural
25 tide cycling could impact organism performance or behavior, while the tide prediction
26 system could additionally be utilized in field experiments where treatments need to be
27 applied at certain stages of the tide cycle.

28 **Keywords:** intertidal, estuary, shore height, *Spartina foliosa*, mesocosm

29 **Introduction**

30 Because of the abiotic and biotic heterogeneity found in intertidal communities, controlled
31 laboratory mesocosm experiments often provide important insight into how these communities
32 function (Dethier et al. 2005; Matassa & Trussell 2011; Stachowicz et al. 2008). Traditional
33 methods of manipulating water level in these mesocosms ranged from completely submerging
34 intertidal organisms to creating tides with fixed submergence depths and rapid tidal changes.
35 Given that tidal conditions (e.g. frequency and length of emersion) drive abiotic conditions in the

36 intertidal zone (Denny et al. 2009), and influence the behavior, performance, and survival of
37 intertidal seaweeds, plants, and invertebrates, there is a pressing need to develop mesocosm
38 systems that create more ecologically realistic tidal conditions.

39 The ebb and flood of tides strongly affect intertidal organisms. For example, the timing of
40 gamete release by seaweeds can be determined by the tides (Pearson & Brawley 1996). For
41 intertidal plants, inundation determines growth (Bonin & Zedler 2008; Padgett & Brown 1999;
42 Ravit et al. 2007), oxygen conductance (Maricle & Lee 2007), and survivorship (Woo &
43 Takekawa 2012). Tidal conditions can also affect animals, including their habitat selection
44 (Davies et al. 2006; Koch 1989; Richardson et al. 1993), parasite release (Curtis 1993), egg
45 hatching (Kellmeyer & Salmon 2001), feeding rates (Charles & Newell 1997; Noël et al. 2009),
46 and movement (Ng & Williams 2006; Silva et al. 2010; Williams & Morrill 1995). Thus, a broad
47 array of organisms is impacted by tidal conditions.

48 Traditional methods of manipulating water level in aquarium tanks have included simple high to
49 low transitions created by removing a drain standpipe to drop the water level, by opening a low-
50 mounted drain valve to drain the tank, or by turning on electric pumps to flood the tank during
51 high tide. These systems often run on a simple fixed daily cycle (i.e. 12 hours high, 12 hours
52 low), or they may be timed to only submerge soil and plants for a few hours during the day
53 (Adams & Bate 1995; Boorman et al. 2001; Paganini et al. 2014). Water levels are normally
54 changed in a binary fashion, with a quick transition from high to low set by the flow rate of the
55 drain pipe. In some cases the transition from high to low water may be prolonged by actively
56 pumping water from the tank at intervals, or carefully sizing the drain pipe to slow the outflow of
57 water (Li et al. 2011; Woo & Takekawa 2012). In a small number of studies, the timing of tidal
58 inundation has been designed to also recreate the natural progression of high and low tide times

59 from day to day, with each maximum or minimum coming later than the preceding day's tide (Li
60 et al. 2011; Miller et al. 2014; Pincebourde et al. 2009). Studies using alternating water levels
61 with estuarine systems have explored the role of tidal submersion on soil salinity, soil water
62 potential, drainage, and the resulting effects on plant growth rates (Adams & Bate 1995;
63 Boorman et al. 2001; Li et al. 2011; Woo & Takekawa 2012). With rocky intertidal systems,
64 these systems have been employed to recreate temperature and desiccation stresses at low tide
65 that could impact animal performance (feeding rate, metabolic rate, and growth rate) under
66 present (Pincebourde et al. 2009) or future climate conditions (Miller et al. 2014) and in concert
67 with additional variables such as water pH (Paganini et al. 2014).

68 We implemented a tide height control system (THC hereafter) for an aquarium system using a
69 microcontroller to calculate the predicted tide height and control a motor-driven drain height
70 adjustment system for continuous depth control. Our goal was to smoothly vary water depth in
71 deep containers holding estuary plants potted in natural soil, creating high and low tide
72 conditions that followed the natural progression of tide heights and timing from day to day while
73 creating drainage in the potted soil similar to what occurs in natural soil in the field. In addition,
74 the goal was to produce a low-cost system that could operate beyond the reach of a persistent
75 network connection and does not require a full laptop or computer to run. Using the THC system,
76 we were able to match the rise and fall of the mixed semidiurnal tides at our nearby field site
77 within our laboratory containers, including accounting for the natural 24 h 50 minute lunar tidal
78 day length that shifts each high and low tide later on each subsequent day. We used this system
79 to examine the effects of tidal submersion duration at different shore heights on the growth rate
80 of the cordgrass *Spartina foliosa* infested with scale insects.

81 **Methods**

82 Tide height predictions for the THC were generated continuously using a stand-alone
83 microcontroller (Arduino Uno, <http://arduino.cc>) with attached real time clock that stored the
84 date and time in local standard time. The microcontroller was programmed to make tide height
85 predictions for the current date and time for the local National Atmospheric and Oceanic
86 Administration (NOAA) tide reference station (San Diego Bay, San Diego, California, USA,
87 mean tide range 1.75 m) using tidal harmonic data generated by the NOAA tide station and
88 extracted from the open-source XTide tide prediction application (<http://flaterco.com>). NOAA
89 tide monitoring stations measure water levels over many years and use these data to generate a
90 set of 37 or more tidal harmonic constituent values that account for the influence of celestial
91 cycles and local topographic features (Hicks 2006). By combining the specific harmonic
92 constants for a tidal reference station with a date and time (used to estimate position of the moon
93 and sun), it is possible to generate current (and past or future) tide height predictions relative to
94 the zero tide datum (Mean Lower Low Water, MLLW). We provide an online archive for the R
95 code (R Development Core Team 2015) used to extract the relevant site data and to generate the
96 Arduino code (C++ code) that runs the Arduino tide prediction routine, along with data for 140
97 NOAA sites around the mainland US, Hawaii, Alaska, and the Caribbean.

98 We used the microcontroller to predict the current tide height every minute, and then actuated a
99 motor-driven rack to raise and lower the drain height of several tanks (Fig 1). The
100 microcontroller interfaced with a stepper motor via a stepper motor controller (see online archive
101 for specific parts lists). The stepper motor drove an acme-thread lead screw (Roton, Kirkwood,
102 Missouri, USA), which moved a traveling nut 0.1 inches per rotation of the lead screw. The
103 controller, motor, and lead screw were mounted in a rack standing 1.2 m tall. A “carriage” was

104 mounted to the traveling nut on the lead screw, allowing the entire carriage to be driven up and
105 down in the rack frame via the lead screw.

106 The aquaria for this experiment were 200 L plastic barrels (88 cm height, 59 cm diameter), with
107 a 3.8 cm bulkhead fit in the bottom to serve as a drain. PVC pipe (3.8 cm) ran from the barrels to
108 the base of the THC rack, where a section of large-diameter hose (1.6 cm ID) connected to the
109 moving carriage on the tide rack. At the carriage, the hose was attached to a PVC tee fitting with
110 the third leg open and oriented straight up. An additional section of large-diameter hose was
111 attached to the opposite leg of the tee fitting and ran to a floor drain. The open leg of the tee
112 fitting prevented the formation of a siphon during operation.

113 The water level in each barrel tracked the height of the rack carriage, so that as the carriage
114 descended, the height of the water in each barrel attempted to equalize with the height of the
115 carriage, causing the water level in the barrel to drop. The incremental shift in height of the
116 carriage from minute to minute resulted in a very small head pressure on the drain hose. If small
117 diameter drain hose was used, adequate drainage would be prevented by the wall drag and
118 surface tension effects until a sufficient head pressure existed in the barrel to overcome that drag.
119 Large diameter hose (1.6 cm) minimized this drag, allowing drainage to proceed even at small
120 water height differentials between the barrel and carriage. During an ascending tide, the barrel
121 water level would fill and rise to meet the new higher position of the carriage on the tide rack
122 until the two heights equalized.

123 We used this system to examine the influence of shore elevation on *Spartina foliosa* (Pacific
124 cordgrass). Elevation has previously been shown to strongly affect growth of a congener (*S.*
125 *alterniflora*) in a field transplant experiment (Bertness 1991). We collected *S. foliosa* and soil

126 from Sweetwater Marsh (San Diego, CA) and brought them to San Diego State University's
127 Coastal and Marine Institute Laboratory. All plants were infested with herbivorous scale insects,
128 *Haliaspis spartina*. Because scale insect density was variable at the time of collection, we
129 counted the density of *H. spartina* on each plant, assigned them to one of five rankings of
130 density, randomly selected one plant from each ranking, and placed plants into replicate barrels.
131 We compared the growth of *S. foliosa* in mesocosms at three shore elevations (2.0, 1.8, and 1.6
132 m above MLLW) which would be submerged for different lengths of time depending on the tidal
133 cycle. These elevations represent the upper end of *S. foliosa*'s elevational range – the highest
134 densities of *S. foliosa* are typically found ~1.0 m above MLLW. We chose the higher elevations
135 because these areas typically have the highest densities of scale insects.

136 Three replicate barrels were positioned at each elevation, with each barrel containing five potted
137 *S. foliosa*. Barrels at different elevations were randomly interspersed amongst each other. The
138 plants were potted in 2.8 liter pots (depth = 17 cm) filled with estuary soil. The pots were
139 elevated inside each barrel so that the surface of the soil in the pot was at a height that would
140 leave it submerged during predicted tide heights above the chosen shore elevation. As the tide
141 dropped, the plant stems and soil would gradually be exposed, and water was able to drain from
142 the soil in each pot. The three shore elevations were established by adjusting the height the
143 barrels relative to the tide rack.

144 The upper travel limit of the THC carriage was defined as 2.07 m above MLLW. The total travel
145 of the rack was limited to 0.84 m, so that the lower travel limit was at a tide height of 1.23 m
146 above MLLW. When the natural tide cycle exceeded the lower (or upper) limit of the THC
147 travel, the carriage halted at that limit until the tide was predicted to rise (or fall) above (or
148 below) that limit again. During these time periods, the water level in the barrel remained equal to

149 the carriage height. During a pilot experiment, we measured the water height difference at the
150 PVC tee on the tide rack and water level in a barrel over a tide range of 0.21 m to ensure that the
151 water level was following the rack movement within the travel range of the THC system. The
152 exact height of the upper limit of the rack could be specified in software on the microcontroller,
153 allowing the re-creation of different tidal ranges depending on the needs of the experiment. The
154 experiment was run for 60 d from July 11 to September 9 2013, during which the maximum
155 predicted tide height was 2.27 m and the minimum tide height was -0.42 m, though the tidal
156 excursion in the barrels was limited to the values given above (Fig 2). The plant height,
157 measured as the distance from the soil surface to the tip of the longest leaf of each *S. foliosa*, was
158 measured at the start of the experiment and every 7-9 days subsequently.

159 Because there were no differences among elevation treatments in the length of the longest leaf at
160 the start of the experiment ($F_{2,51} = 0.85, p = 0.44$), we measured plant growth as the difference
161 between the maximum leaf length and starting leaf length. Additionally, because we did not
162 observe an effect of starting insect density on plant growth, we pooled all plants within each
163 barrel to account for the nesting of five plants in each barrel (thus, we had a single growth value
164 for each of our three replicate barrels for each elevation). Upon examination of the data, we
165 observed heterogeneous variances between our elevation treatments and so analyzed our data
166 with a Kruskal-Wallis test.

167 We also calculated scale insect population growth by dividing the maximum number of scales
168 per stem by the starting number of scales per stem. This provided us with insight into the
169 performance of scales at each elevation. Although scale dispersal primarily occurs on the natal
170 plant (J. Long, pers. obs.), we pooled all plants within each barrel to account for the lack of

171 independence. As with plant growth, we analyzed the data with a Kruskal-Wallis test. Analyses
172 were carried with R 3.1.3.

173 **Results**

174 Predictions from the THC tide calculation algorithm matched predictions from NOAA
175 predictions (<http://tidesandcurrents.noaa.gov/>) within 1 cm at all times. Water levels in the
176 aquaria barrels followed the height of the tide rack within 1-2cm (1.25 ± 0.4 cm, mean \pm 1SE),
177 so that realized tide heights in the barrels followed the predicted rise and fall of the tides, within
178 the travel limits of the tide rack. The upper limit of the tide rack travel (2.07 m) was set slightly
179 above the soil surface of the highest elevation treatments in our mesocosm experiment. The soil
180 in the two lower elevation treatments was completely inundated on 49 occasions (tides above 1.6
181 m elevation) and 23 occasions (tides above 1.8 m elevation) during the 60 day experiment, while
182 the soil in the highest elevation treatment was only covered on 11 days (Table 1).

183 The growth of *Spartina foliosa* depended upon tidal height, with lower plants growing more than
184 twice the amount of higher plants (Fig 3a, Kruskal-Wallis test, $H = 6.489$, $p = 0.039$). In contrast,
185 the population growth rates of scale insects did not depend upon tidal height (Fig 3b, Kruskal-
186 Wallis test, $H = 2.222$, $p = 0.329$).

187 **Discussion**

188 The ability to recreate natural cycling of tide height and timing allows researchers to better
189 control what may be an important aspect of laboratory mesocosm experiments for estuary or
190 rocky shore systems. We present a simple, standalone microcontroller system that generates real
191 tide predictions, without the need for an external network interface, and that will automatically

192 resume function following loss of power. Because the THC system's real time clock carries a
193 backup battery to retain the date and time, an interruption of power will result in the system
194 rebooting and returning to the current predicted tide height when mains power is restored. These
195 predictions are coupled with a novel motor-driven rack system to continuously manipulate the
196 standing height of water in an aquarium, allowing smooth changes in tide levels.

197 We used the THC system to observe the effects of different tidal inundation durations on
198 *Spartina foliosa*, a native cordgrass in marshes on the west coast of North America. Members of
199 the genus *Spartina* have differing tolerances for the amount of time they spend submerged, and
200 many estuaries exhibit a marked zonation in marsh plants with increasing tide height. The
201 transition between different marsh plant species across shore elevation gradients is driven in part
202 by competition and herbivory, but can also be a result of edaphic conditions influenced by the
203 tide (Bertness 1991). In this mesocosm experiment, reduced leaf elongation was associated with
204 the prolonged aerial emersion produced by our higher shore elevation treatments.

205 In this experiment we simulated the tide cycling at a high shore height (1.23 to 2.07 m above
206 MLLW), leaving the *S. foliosa* exposed for much of the time. The THC system can easily be
207 adapted to simulate lower-shore submersion and emersion regimes by changing the reference
208 shore height in the controller software. For example, if the goal was to recreate conditions in the
209 0 to 0.84m shore height range (or any other range), changing a single value in the software could
210 set the rack upper limit to be 0.84 m above MLLW. In this scenario, the THC rack would then
211 alter the water level in the barrel whenever the predicted tide moved between 0.84 and 0 m, and
212 the barrel would remain full whenever the predicted tide was above 0.84 m. If the researcher
213 desired a larger range of movement, then deeper aquaria and a taller THC rack could be built,
214 and only two values in software (upper limit and available rack travel) would need to be

215 adjusted. The motor driven rack in this experiment was set up to drain nine separate aquaria, and
216 additional aquaria could be included by modifying the system to use a more powerful motor to
217 lift the weight of additional drain hoses.

218 Outside of the application described here for controlling water height in an estuarine mesocosm
219 experiment, the THC tide prediction function could be used in a number of other scenarios. The
220 system can be adapted to control aquarium flow in simpler high/low tide regimes that may still
221 require a natural progression of the timing of high and low tide from day to day. The
222 microcontroller tide calculations described here have been used to actuate an electric drain valve
223 mounted on the bottom of a tank, so that a closed valve forces the water level to rise and exit via
224 a high mounted drain at high tide, while an open valve causes the water level to drop to simulate
225 low tide. Alternatively, the controller has been used to regulate the delivery of water spray so
226 that it only occurs during high tide periods, simulating the periodic inundation created by wave
227 action. This implementation has been used to successfully maintain rocky intertidal grazers such
228 as high shore *Lottia* limpets that dislike being permanently submerged (Miller et al. 2015).
229 Finally, the small size and lower power consumption of the microcontroller system allow it to be
230 used in field locations where it can be powered by battery or solar cells. Lee et al. (personal
231 communication, D. Lee, Virginia Commonwealth University) used the tide predictions generated
232 by this system to control the timing of water release in an estuarine field experiment aimed at
233 manipulating the duration of soil surface wetting to imitate the effects of higher sea level. In a
234 scenario such as this, where manipulations need to be timed to coincide with the constantly
235 shifting tide cycles in order to conserve power or supplies, our system can allow accurate timing
236 and will run for long periods of time on minimal power. The Arduino microcontroller making the
237 tide predictions consumed about 20 mA in the original configuration (not including the motor

238 driven rack), but this power draw could be reduced to 0.3 mA or less with alternate Arduino-
239 compatible microcontroller hardware and software changes. The microcontroller could also be
240 easily modified to track and manipulate other environmental variables in addition to tide height,
241 such as temperature or light, and to serve as a datalogger, using inexpensive commercially-
242 available modules developed by the open source community.

243 The software libraries provided in the online materials are presently limited to sites for which
244 NOAA freely provides data under its mandate that United States government products be made
245 available to non-commercial and commercial users. Many other countries make their tide
246 harmonic data available only as a commercial product, but if the user can gain access to the tidal
247 harmonic constituents for their site elsewhere in the world, the underlying open-source tide
248 prediction software used here can be updated to substitute those values, as described in the
249 Arduino C++ source code provided in the online archive.

341

342 **Tables**

343 Table 1. Summary of the number and duration of events where the soil surface of plant pots was
344 submerged by a high tide event. The experiment ran for 60 days (1440 hours).

Shore Height (m)	Number of days with	Total hours with soil	Percentage of time
	soil surface		with soil surface
	submergence event	surface submerged	submerged
1.6	49	161	11.2
1.8	23	58	4.1
2.0	11	22	1.5

345

346

347 **Figures**

348 **Fig 1** Functional diagram and illustration of the tide height control system. The microcontroller
349 system is contained within the box at the top of the rack. A motor contained in the box drives the
350 central lead screw of the rack up or down in time with the tide, raising or lowering the traveling
351 rack carriage to change the height of the drain for the aquarium tank (88 cm tank height in this
352 experiment). The water level in the tank will naturally equalize with the height of the traveling
353 carriage. Multiple tanks can be controlled simultaneously by running each drain hose to the
354 traveling carriage of the rack, and the simulated shore height of the tanks can be changed by
355 adjusting the height of an individual tank relative to the rack, while the rack can also be
356 programmed to travel within different ranges of the tide excursion.

357 **Fig 2** Predicted tide cycles for San Diego Bay during the 60 day experiment from July 11 to
358 September 9 2013. The dark region represents the tide range that the tide control rack was
359 capable of traveling through. Water height was held static at the upper or lower limits of the dark
360 region when the natural tide exceeded the travel limits of the tide rack. The heights of the
361 *Spartina* pots are *shown* at the right.

362 **Fig 3** Growth of *Spartina foliosa* plants (a) and proportional growth of scale insect populations
363 (b) in mesocosms connected to the tide controller at three elevations. Values are mean \pm 1 SE, n
364 = 3 replicate barrels per tide height.

365

366 **Fig 1** Functional diagram and illustration of the tide height control system. The microcontroller
 367 system is contained within the box at the top of the rack. A motor contained in the box drives the
 368 central lead screw of the rack up or down in time with the tide, raising or lowering the traveling
 369 rack carriage to change the height of the drain for the aquarium tank (88 cm tank height in this
 370 experiment). The water level in the tank will naturally equalize with the height of the traveling
 371 carriage. Multiple tanks can be controlled simultaneously by running each drain hose to the
 372 traveling carriage of the rack, and the simulated shore height of the tanks can be changed by
 373 adjusting the height of an individual tank relative to the rack, while the rack can also be
 374 programmed to travel within different ranges of the tide excursion.
