Abstract
Attempts to infer the ecological drivers of macroevolution have long drawn inspiration from work on extant systems, but long-term evolutionary and geological changes complicate the simple extrapolation of such theory into a deep-time setting. Recent efforts to incorporate a more informed ecology into macroevolution have moved beyond the descriptive to attempts that seek to isolate the generating mechanisms of dynamic signatures to produce testable hypotheses of how species and larger groups usurp or co-exist alongside one another over vast spans of time. The papers of this Theme Issue exemplify this progress, providing a series of case studies of how novel modelling approaches are helping infer the regulators of biodiversity in deep time. In this Introduction, we aim to discuss the challenges associated with this area. We break our Introduction into four main areas. First, we discuss how our choices of biological units for study have implications for the conclusions subsequently drawn. Second, we emphasize the need to embrace the interdependence of biotic and abiotic change, because no living organism ignores its environment. Third, in the light of parts 1 and 2, we discuss the set of dynamic signatures that we might expect to observe in the fossil record. Finally, we ask whether these signatures are the most ecologically informative foci for research efforts aimed at inferring the regulators of biodiversity in deep time. The papers in this Theme Issue contribute in each of these areas.
1. Introduction

Organisms respond to their environments. This link regulates biodiversity, but its complexity complicates efforts to provide unequivocal evidence for supposedly fundamental observations. The challenge in deep time is to unpick how environmental, ecological and evolutionary processes interact when they cannot be observed directly.

Palaeobiology and evolutionary biology have long drawn inspiration from methods initially developed for population ecology [1, 2], where the chief regulator of biodiversity is often purported to be density-dependence: population growth rate falls as population size increases due to resource limitation [3]. The co-option of population ecological theory into palaeobiology has a distinguished history [4], but this simple re-interpretation of elementary ecology is compromised by the vast time scales, which provide scope for environmental, (micro)evolutionary and geological change. Simple plots of species’ diversity through time reveal coarse dynamical patterns of how the diversity of life on Earth has fluctuated, but do not uncover which underlying mechanisms generate such higher-level patterns [5].

The outcomes of interactions among living organisms can be experimentally manipulated to tease apart direct causes of births and deaths. These interactions can have negative (competition, predation) or positive (mutualisms, symbioses) consequences for a focal species. The outcome of the interactions depends on the abiotic arena in which those species co-exist: the victorious species in competition is the one that can persist on the lowest amount of the limiting resource [6]. It is difficult to move from small-scale experiments to large temporal and spatial scales [7] because of substantial changes in the terms of reference: carrying capacities in population biology restrict population growth directly by resource limitation [3, 8], whereas an analogous limit at supraspecific level, and over hundreds of thousands or millions of years, is an emergent higher-level phenomenon from genuine interactions among individuals moving together through space and time.

Traditionally, deep-time regulators of biodiversity have polarised into biotic vs abiotic controls [5], with biotic interactions argued to dominate in the near term and abiotic upheaval imparting the clearer signal over long time scales [9]. The biotic, organismal, ecological perspective is commonly associated with the Red Queen hypothesis originally proposed by Van Valen to explain the age-independent extinction probabilities among ecologically homogeneous groups [10]. In his original formulation,
Van Valen considered the deterioration of the environment to include both the biotic and abiotic environment, but palaeontologists have, for pragmatic reasons given the coarseness of the rock record, usually credited most biodiversity change to abiotic factors [9, 11]. The false dichotomy between the supposed superiority of biotic versus abiotic factors in regulating biodiversity [5, 9, 12] echoes the analogous debate in population ecology [8]. While population ecologists concluded that the abiotic environment acts as soft tissue on top of a hard density-dependent “skeleton” [8], ecologists working in deep time have to acknowledge that the resource limitation “skeleton”, on which everything supposedly hangs, is nothing more than an emergent property from accumulating organismal responses to the biotic and abiotic environments with which they interact. These organismal responses are liable to evolve substantially through time.

Evolutionary rates multiply by many orders of magnitude when measured at laboratory scales of days and months, historical time spans of years and decades, and palaeontological spans of millions, or hundreds of millions, of years [13]. Analysts are in effect measuring different aspects of a single fractal phenomenon where some rates are generational changes, while others are the outcomes of phenomena averaged over long-term environmental change. Most palaeontologists will never be as confident as experimental biologists that the individuals and species they study genuinely interacted at a given time in a given location, but that does not mean that progress towards studying biotic interactions in deep time is impossible. Indeed, progress towards more ecologically informed macroevolution has shifted over the past five years from a predominantly descriptive pattern-based approach [14], to one in which we now aim to isolate which ecological mechanisms determined the origination, proliferation and extinction of biodiversity.

This Special Issue aims to synthesize this progress. Our introduction to the manuscripts, which reviews the state of the art and showcases advances in contemporary modelling and data extraction techniques, lays the foundations required for methods to extract the generating mechanisms. We begin with how our analytical choices affect the results we obtain.

2. Individuals, populations, species and genera
Although ecologists can characterize biodiversity more broadly than simply counting species, most deep-time studies cannot directly quantify abundance or biomass data. Deep-time investigations into the regulators of biodiversity are, for the most part, limited to counting taxonomic units through time. Linnaeus wrote in *Fundamenta Botanica* that both genus and species are genuine entities of nature [15]. Mayr [16] argued that species, now considered the canonical unit for macroevolution, obey ecological rules, but conceded also that genera represent a biological reality. The integrated taxonomic evidence that multiple genera occupy morphospace discontinuously and rarely hybridize among themselves due to their long histories of separation [17] support the basic tenet for reproductively isolated taxonomic units. The same could be argued for any higher, clade-based taxa, whatever category names one might wish to apply, provided they reflect fundamentally different organismal constructions.

Acknowledging all the vagaries of matching category terms to clades, Benton [18] showed broadly similar genus and species diversity curves, both of which differed markedly from the corresponding higher order and family curves. The smoothness at higher taxonomic levels (e.g. families and orders) and the apparent evidence for upper limits to diversity [4, 18] is, in part, a function of artificial constructs (naming by scientists), in part incompleteness and structure of the rock record [19, 20] and also some genuine biotic interactions. A logistic curve at the level of orders or classes might reflect increasing diversification at species level within a continuously branching tree [18], but need not correspond in any simple way to lower-level processes: the marine invertebrates, for example, show a single equilibrium without the component clades doing so [21].

Given that morphology and species classification within taxa are not necessarily coupled, the different diversity trajectories among different levels of the taxonomic hierarchy [18] result in part from anthropogenic conventions that influence extinction risk. Raup [22] proposed that if species follow Van Valen’s law [10] of random extinction with respect to age among homogeneous groups, then genera cannot, and vice versa. There is a difference between the durations of species and genera because species’ longevity is solely determined by extinction, assuming genuine speciation occurred in the first instance, whereas the longevity of a genus is determined by both speciation and extinction of the constituent species. Additional confusion of
macroevolutionary longevity arises through pseudospeciation and pseudoextinction [23],
which occur when sufficient anagenetic change causes scientists to award a new name
to a novel morphological form despite a lack of cladogenetic lineage splitting. These
pseudospeciated morphospecies are therefore often named from the anagenetic
appearance of a novel character rather than post-speciation divergence from an
ancestral species.

To illustrate how taxonomic practices and taxonomic resolution impact our ability
to reject fundamental evolutionary laws, we analysed durations of Cenozoic Era
macroperforate planktonic foraminifer morphospecies (defined by the first appearance
of a novel character), evolutionary species \textit{sensu} Simpson [defined by the first
appearance of a morphological gap, i.e. post-speciation divergence, between sister taxa,
23, 24, 25] and genera [26]. To ensure we were comparing homogeneous groups of
species [10], we followed [12] and corrected for a changing environment using the
Zachos et al. [27, 28] $\delta^{18}$O oxygen isotope compilation of deep sea benthic carbonates,
the natural logarithm of the number of contemporaneous morphospecies, evolutionary
species or genera (as appropriate) as well as morphological innovations associated with
feeding ecology and depth habitat at the beginning of each duration. This assumption
encodes the idea that conditions early in a species’ or genus’ existence leave long-lasting
signatures on its duration [29]. Morphospecies and evolutionary species show age-
specific patterns of extinction: the youngest species are most likely to go extinct. The
genus durations, on the other hand, cannot be distinguished from Van Valen’s law of
constant extinction (Fig. 1), consistent with Raup’s prediction [22]. Interpreting these
numbers, including the possibility that the age-specific extinction patterns in species are
nothing more than a veil line (implying we fail to document the shortest-lived species)
demonstrates how analysing different levels of the Linnaean hierarchy can generate
different extinction risks during a taxon’s existence. Altered extinction risks change
species longevities, which, as a consequence, change any inferred diversity-dependent
regulation [25].

The empirical correspondence between the species and genus diversity curves
[18] should not therefore be taken to imply that analyses at either species or genus level
are equivalent. Genus-level origination encodes substantially more divergent ecologies
than those perceived by speciation: higher taxonomy is, in one sense, a crude index of
morphological disparity through time [30]. If speciation is in fact a rather easy and
common process that constantly produces ecologically similar species [31], then it could be argued that the limits to long-term equilibrium models of diversification [32] are not regulated by speciation but rather by origination of evolutionarily significant units at higher taxonomic levels [33-36]. Equilibrial assumptions are more common for species level analyses performed by neonatologists than analyses on higher taxa [37], which contradicts the empirical paleontological evidence [18] and standard paleontological practise [4, 21, 38-40].

The assumption that the species is the canonical unit of study has long held, but the inconvenient truth is that a species, like all higher-order taxa in the Linnaean system, contains heterogeneous amounts of intraspecific variation through the spatial organisation of populations and cryptic genetic types. The reality is that genera and species both contain relevant, but distinct, information for what regulates biodiversity over long time scales. The re-emergence of the biological reality of higher taxa has in part been stimulated through the increasing size of molecular phylogenies, and thus statistical power, to identify multiple thresholds which make it clear that molecular diversification cannot be explained by species-level divergences alone [33, 34]. The more resolved level exhibits greater fluctuations [4], which may or may not be of genuine biological interest in terms of identifying the principles behind patterns of biodiversity.

3. Biotic and abiotic contributions to stochastic macroevolutionary dynamics

Sepkoski argued that a stochastic version of his fixed finite upper limit to taxon diversity was “probably more typical of natural systems” than the deterministic analytical solutions [4]. Population ecologists have long used year-to-year fluctuations in abundance to reveal that environmental stochasticity acted on a density-dependent framework [8]. One simplistic partitioning [41, 42] is that the cause of any deviation from a deterministic density-dependent framework is either due to an environmental factor that affects the realised fitness of all individuals concurrently (environmental stochasticity: $\sigma^2_e$), or due to winners and losers from particular individual interactions that average out in the long term (demographic stochasticity: $\sigma^2_d$) such that:
Demographic stochasticity is defined by a sum of squares statistic for the relative variation among individual fitnesses in a given time interval. Environmental stochasticity is calculated by the residual of observed vs. expected change, minus the difference caused by individual interactions [43], and therefore assumes a uniform response (e.g. an increase in background origination rates) in all individuals. While this binary classification forms a crass straw man, this simplistic polarisation echoes the palaeobiological dichotomy into either the biotic, organismal Red Queen school [10, 44], or its supposed abiotic, environmental Court Jester alternative [11]. The mutual dependence between the hypotheses has only recently been acknowledged [5, 9, 12].

Assuming that the number of species saturates following logistic growth [4], calculating environmental and demographic stochasticity statistics for evolutionary species of Cenozoic Era macroperforate planktonic foraminifera [26] suggests that differential responses among species explains, on average, about three times as much variation as the changing environment (0.087 vs. 0.029). This result is unsurprising. The waxing and waning of relative abundance reported at species [12, 45] and genus levels [21, 46], as well as among higher taxa [47], is evidence that there are always winners and losers from environmental change. In deep time, the key challenge is to identify why some groups of species are winners and others losers, beyond the expectations of patterns that can be generated assuming neutral dynamics [48, 49].

The stochastic population theory used above [41, 43] predicts that environmental stochasticity will dominate dynamics for sufficiently large populations (i.e. $N$ large) such that the differences among individuals can therefore be neglected. The species-area relationship is one of the best ecological laws in determining the number of species that can co-exist within a given biome, but, in terms of driving macroevolutionary diversification shifts in deep time, the fragmentation of the area has been argued to be as influential as area per se [50, 51]. In this volume, Jordan et al. [52] find that neutral theory, in which all species are assumed to be functionally equivalent [48], on a fragmenting super-continent cannot explain the post-Jurassic increase in terrestrial species richness. The results imply a role for some biotic factors, either a competitive advantage or some other founder effect over and above geographic isolation, in the

$$\sigma_{\lambda}^2 = \sigma_e^2 + \frac{\sigma_d^2}{N}$$
subsequent adaptation and expansion of the clade, even if the precise generating mechanism remains to be identified.

The third fundamental cause of stochasticity is measurement error [42]. Palaeontologists have to worry about the fossils that enter the rocks and which fossils are found [53]. Preservation biases include organismal factors (skeletons or not; slow or fast reproducers; population size), their habitats (marine and lowland settings are more often preserved than uplands and forests), and the subsequent history of the rock (is it eroded or buried; is it metamorphosed or not; is it covered by younger rocks?). Human biases include accessibility (is the rock at the surface; is the rock in reach of people?), geographic location (e.g. Europe vs. South America), and research interest (e.g. diatoms vs. dinosaurs). On the whole, older rocks survive less completely than younger rocks, and much emphasis has been placed on this temporal pattern: Raup [53] and Alroy [21] argue that this bias explains nearly all of the substantial rise in biodiversity through the Phanerozoic, and tie this to a model in which global biodiversity reached modern levels over 400 Myr ago.

The biased distribution of fossils in time and/or space motivated development of methods to “correct” for the vagaries of the rock record [54-59]. Commonly used sampling proxies, such as counts of collections, localities, or formations, accrue in close connection with the species count [60]. Residual-based approaches [56, 57] compare a sampling proxy (e.g. formations count; rock outcrop area) and then identify and remove a sampling trend, with the residuals interpreted as the true biological signal. Acknowledging the limitations of formation counts as a suboptimal sampling indicator, it remains controversial whether the correlation between rock and species counts, or the residual from that correlation, represents the holy grail of biological truth [60]. Rarefaction [54] and shareholder quorum subsampling [21] have proven less controversial methods, but still imply that the geological drives the biological. Integrated approaches, which calculate the error due to incomplete preservation and biological diversity simultaneously, promise to place both on an even footing [58, 59, 61-63].

In this volume, Starrfelt & Liow [64] claim to have identified a method to identify true levels of bias, and so true levels of former biodiversity, for particular clades in the fossil record. The new TRiPS method (True Richness estimated using a Poisson Sampling model) is based on the assumption that a particular fossil species, if observed
multiple times in a given time interval, has a relatively high probability of fossilization and discovery by palaeontologists. Starrfelt & Liow apply their method to the fossil record of dinosaurs, and estimate that there were 1580 genera and 2983 species of dinosaurs in all, and that the numbers tramping across the Earth at any time ranged up to 300 in the latest Cretaceous, when diversity was highest. If the method is bulletproof, it could revolutionise the ways in which palaeontologists and evolutionists in general treat fossil record data on ancient biodiversity.

The difficulty of extracting the biological signal from the geological noise was formalised by Raup et al.’s [65] pioneering work simulating phylogenetic diversification. At a given point in time, Raup et al. [65] assumed that each species has an equal probability of going extinct and an equal probability of giving rise to a descendant daughter species. These assumptions evoke the equal rates Markov model of diversification [49] and Hubbell’s Neutral Theory [48] for a clade fluctuating around its supposed equilibrium (assuming, in the latter case, that the birth and death rates are similar). A simple null model with constant rates was able to recover the diversity trajectories seen in the fossil record [65]. “Familiarity with the ‘patterns’ that random processes create is ... essential” for all scientists [49] because “it is fatally easy to read a pattern into stochastically generated data” [66]. Systematic geological structure can generate seductive impressions on macroevolutionary signals, such as bursts of genus origination [20], the clumping of last occurrence dates into apparently accelerated extinction events [67] as the ranges of higher-taxa are bounded by mass extinctions [68]. It has now become standard to model time series against random walks to take account of this major concern.

Despite this warning for any literal reading of the fossil record [65], running the same simulations using empirically defined parameter estimates suggested that the fluctuations in fossil taxon counts most likely result from changes in the diversification dynamics rather than a constant-rate stochastic process [69]. Asserting a role for ecological regulators of biodiversity requires the rejection of appropriate stochastic null models that incorporate the temporal inconsistencies of fossilisation [49].

4. The regulators and their signatures
Macroevolutionary diversification is the net outcome of speciation and extinction. The regulators of biodiversity act differentially through these two rates as different ecologies compete with each another, filtering global biotic and abiotic environmental change, to shape variation among contemporaneous species in their speciation probability and extinction risk (Fig. 2). Understanding the interplay between organismal biology and environmental change holds the key to identifying the generating mechanisms of macroevolutionary dynamics [12].

Although fossil data are increasingly being used in phylogenetic comparative methods [62, 63, 70], the key interaction between biology and the environment is still rarely incorporated. This is in part explained by the lack of methods, but also to the nature of the data. Phylogenetic studies using only extant taxa often reconstruct evolutionary history from a single time slice and are therefore blind to dynamic associations between biological and environmental change, as well as sequential evolutionary changes that influence the evolutionary fate of lineages [71]. This coupling of the biotic response to abiotic environmental change emphasises one limitation of a simple extrapolation of population ecology theory into a macroevolutionary context. Sepkoski [4] assumed a single fixed equilibrium level of species diversity, which is a strong assumption if we hypothesise that environmental resources affect the outcome of competition [6] in deep time [38, 72].

Competitive interactions are probably the most commonly discussed biotic driver of diversification rate changes. Both origination and extinction rates have been reported as diversity-dependent and both can generate equilibrial dynamics in biodiversity [4, 73, 74]. At a finer taxonomic resolution than assumed by Alroy [73] or Foote [74], speciation rate seems to respond more closely than extinction rate to changes in intraspecific diversity [Fig. 3, see also 12, 38], but this balance of influence need not be constant for all time [74]. Species interactions are increasingly being recognised as able to leave an impact on clade diversification through a variety of modes [75, 76] and not simply slowdowns in diversification rate with increasing levels of standing diversity [77, 78].

The dominant mode of XXX likely depends on how the arena for competition is defined. Unlike the case in Figure 3, which analyses the whole Canidae family as a homogeneous unit, Silvestro et al. [45] reported little diversity-dependent speciation within each Canidae subfamily as a distinct guild [79] and evoked interspecific
competition among subfamilies in a broader species pool, in which all species compete for similar resources. Under such a scenario, clade replacement selectively drives less competitive guilds to extinction [79]. This difference between Figure 3 and Silvestro et al. [45] leads to the more refined hypothesis that biotic competition between closely interacting groups of species will leave a signature in extinction rates, whereas competition within closely interacting groups of species will leave a signature in speciation probability.

Developing this line of thought, Marshall & Quental [80] explore the hotly debated question of limits on diversification [32, 72]. Verbal interpretations of a diversity dependence mechanism built into a dynamic carrying capacity exist [32, 81], but an environmental regulator of such dynamic limits has not been identified statistically. Marshall & Quental [80] argue that an appropriate definition of the species pool and the consideration of time-variably carrying capacities could reconcile evidence for and against the ideas of bounded versus unbounded diversification. The authors propose a diversity-dependent modelling framework with a carrying capacity varying through time as a result of changing either intrinsic diversification rates or the strength of the diversity dependent effect. Importantly, their approach allows resolution of a long-standing debate about whether total global biodiversity has been held at equilibrium levels for long spans of time, or whether global biodiversity never reaches such levels.

Biogeographical variation fundamentally restricts such global-level analyses. Debates about the origin of the latitudinal diversity gradient exemplify this problem. The latitudinal diversity gradient is one of the most frequently described macroecological patterns [82], but has not been constant through time [83]. The tropics are cited as acting as both a cradle of and a museum for diversity [84, 85], with the consequence being that these biomes act as net exporters of biodiversity to other regions [85, 86]. In this volume, Fenton et al. [87] investigate the deep-time causes of the modern latitudinal diversity gradient in calcareous zooplankton. The authors construct latitudinal diversity gradients in deep time as an independent dataset to assess whether any putative driver has a dominant underlying cause or reflects multiple factors acting in concert [84, 85], including the statistical artefact of the mid-domain effect [88]. Fenton et al. [87] demonstrate no latitudinal gradient at the beginning of the Eocene epoch, but that the modern day latitudinal diversity gradient was established by the Eocene-Oligocene Transition 33.7 Mya.
If specialist species depend intimately on their native biome to persist, then any climate change that alters the spatial extent of these biomes will rapidly lead to their extinction. Exploring the interactions of species and their geographic ranges over ecological and evolutionary time scales has been hard. In this volume, Villalobos et al. [89] explore how species co-occur with other species, and find that in the long term species respond individualistically to major climatic shifts, while more stable climates allowed less phylogenetically variable, yet richer palaeocommunities to settle. The authors calculate phylogenetic fields, the co-occurrence patterns among species and their phylogenetic structure within individual species ranges, for living and extinct mammal species over long spans of time, to explore how individual species interact with predators, prey, and competitors, and with major changes in physical environments.

Although these methods can be readily applied in deep time, reconstructing species interactions is only useful when the spatial distribution of communities can be accurately estimated. The preservational biases of the fossil record are exacerbated when variations through space and time are to be addressed. In this volume, Silvestro et al. [90] develop flexible new approaches incorporating multiple patches, and patch sizes, that use fossil data to infer macroevolutionary and biogeographical processes while taking into account the incompleteness (temporal and spatial) of the fossil record [91, 92]. The impact of migration is not symmetric [90, 93], implying a role for biotic interactions among already existing species and the new invaders in determining macroevolutionary fates. A major problem with most methods that use extant data only is the fact ancestral geographic ranges inferred from phylogenies might be blind to local past extinction and temporal changes in the asymmetry of dispersal rates. Silvestro et al. [90] applied their method to a genus-level empirical dataset of Cenozoic non-marine vascular plants. Their empirical results suggest a predominant dispersal from Eurasia to North America in the Eocene climatic cooling period, but a higher dispersal from North America to Eurasia during the more stable climatic period between 32 and 14 Ma. The most recent 10 My are characterized by a more symmetric dispersal between both continents, although higher extinction rates in Eurasia.

Empirical studies focus increasingly on geographical range as a predictor of extinction, but evidence is mixed: Dunhill & Willis [94] find no evidence that geographical range drove extinction dynamics in terrestrial vertebrates at the end-Triassic crisis, while higher overall diversity occurred when Phanerozoic marine...
invertebrate occupancy was restricted to a single biome [95]. Geographic range forms a composite trait not expressed by individuals but by the populations they form, i.e. is another problematic emergent phenomenon from lower-level processes. While space can reveal the extent of a given ecological interaction, and different spatial extents impact the probability of speciation [96] and extinction [41], unpicking the role of that interaction requires identification of the characters that define the functional role of species and the impact these functions have on their communities [97].

5. Beyond counts and towards ecological significance.
While most deep-time studies on biodiversity dynamics focus on counting taxa (however defined), such counts have limited ability to indicate ecosystem functioning [98]. Phenotypic traits provide this ecosystem functioning and determine the ecological redundancy of given species within a community [99]. Experimental studies indicate that initial species losses have relatively little impact on the healthy functioning of the ecosystem, but that increasing drops in species richness provoke increasing declines of functioning through non-linear feedbacks [100].

The limitations of taxon counts as a coarse presence/absence metric for inferring the link between organism and its environment have long been acknowledged, as have those of simply measuring abundance. "It is time we stopped simply counting taxa and tracking their numbers over time, and began looking at them, measuring them and estimating their ecological roles" [101].

More informative dimensions exist and better describe the state of a given assemblage or community [87, 98, 102]. Missa et al. [103] use computer simulations to show, under Neutral Theory [48] with alternative modes of speciation, that species richness attains its equilibrium before an equivalent asymptote for ecological patterns (first species area relationships [SAR] and then species abundance distributions [SAD]). Phylogenetic patterns of biodiversity either do not (e.g. phylogenetic diversity) or take far longer (e.g. tree imbalance and gamma statistics) to converge. The authors also show that the mode and magnitude of speciation strongly affect the time for ecological patterns reach their equilibrium. The time to reach equilibrial phylogenetic patterns differed among speciation modes: the gamma statistic [104] converged more quickly assuming a “point mutation” mode of speciation. The authors conclude: “Given that real
metacommunities may not have reached equilibrium in terms of species richness, it would be unwise for users of the Neutral Theory of Biodiversity to continue assuming that other biodiversity patterns, taking even longer to converge to equilibrium, are themselves at equilibrium.”

One of the reasons for the resurgence of interest in higher taxa is that they, if robustly defined, are more intimately linked to environmental change than species. The environment moderates both the number of ways that organisms can persist, and also the efficiency of the chosen method: the number of hypercarnivores has been roughly constant through time, despite ongoing turnover in named species [105]. The principal way in which functional types are defined in deep time is by assigning roles to particular characters [106]. Mass extinction events generate high levels of species extinction, but might only slightly reduce [107] or considerably change [108] or ecological function. Although taxon diversity and morphological disparity are not always coupled [109], morphological disparity typically saturates more rapidly than taxon diversity counts [110]. Obtaining accurate estimates of intraspecific variation is fundamental to adoption of trait-based approaches for their use in inferring niche breadth and stability, as well as the strength of ecological interactions [111, 112]. Understanding changes in the ecological role of a given species, and studying how trait distributions change more broadly, therefore could reveal species interactions. In this volume, Hsiang et al. [113] describe algorithmic procedures to rapidly extract size and shape phenotypic data in microfossil communities, providing the robust sample sizes from which trait (co)variation can be accurately estimated. A focus on morphological traits promises to “bind the past and present together” [114] as a common analytical currency for analysis in deep time and the present day. The challenge ahead is therefore to identify ecologically meaningful traits that are incompletely rendered by higher taxon definitions [114, 115].

Although the fossil record is the most direct way to access the role of different regulators [71], it has also, until recently, been blind to preservation of certain body parts and physiological functions that might be ecologically very relevant. Here, Trueman et al. [116] review ecogeochemical methods as used to study food web structure, nutrient fluxes and animal movements in contemporary deep sea fish systems. Deep-sea fishes share with fossils many of the problems in extracting trait data: difficult-to-access material and vanishingly rare evidence of direct interactions.
among individuals. The authors provide a balanced perspective of the potential impact of the approach. While evidence exists that symbiosis influences macroevolutionary dynamics in deep time [12], other areas are less well understood: trace element analysis can indicate gene flow in the focal modern deep sea fishes, but remain unproven in deep time [116]. Adoption of such techniques promises a more holistic (beyond morphology) view of the interplay between organism and its environment in deep time.

Selection pressure and long-term rates of evolution are regulated by ecological opportunity [117], but any response to selection depends on individual form [118, 119]. Individual form matters because individuals in species are characterised by a distinctive set of traits, many of which covary. It is not individual traits that survive, reproduce and die, but whole individuals. Selection on one trait can generate a response to selection in others [119], implying that we need multivariate approaches within functional modules [120]. The decoupling of size and wing shape, for example, differs among distinct subfamilies of fossil birds and occurred as a precursor to flight [121]. Despite Simpson’s evocative “choppy sea” metaphor of a dynamic adaptive landscape [122], there are “dismally few” empirical estimates of how the constraints imposed by trait covariance evolves during a species’ existence [123].

Multivariate changes in ecologically relevant traits offer strong potential to better understand the processes that bridge micro- and macroevolution [124]. If there are no strictly macroevolutionary processes [125], then we need a finer resolution to unpick what is different in making ecological divergence stick through some speciation events, but not in others. Coarse macroecological proxies, even when calculated as integrated variables over the whole duration of each lineage [126], show negligible explanatory power to predict molecular divergence, albeit among a very limited number of species [127]. It is now widely accepted that evolutionary divergence can be rapid [13, 128], and its rate covaries negatively with the interval being studied [13]. While diversity dynamics need the fossil record to understand the dual roles of speciation and extinction [71], fine temporal resolution might reveal that the ecological regulators of biodiversity actually operate chiefly in a punctuated fashion during post-speciation divergence, rather than once species-specific roles and interactions are established.

6. Conclusion

"It is my hope that future work will not reject the question of competition
in macroevolution out of hand, but will explore it with new models that
are more sophisticated than coupled logistic equations and can use these
accumulating paleontological data to produce far more predictive, and
therefore testable, statements about how species replace one another
over the vast spans of evolutionary time". [129]

The challenge is not finding a dynamic signature of ecological interactions in
macroevolutionary dynamics, but rather in isolating a particular generating mechanism
from the many sources of bias, role of random chance and disparity of potential
outcomes. Continued dialogue and ever-closer union of fossil and modern approaches
will prove essential in maintaining this momentum [130]. It is difficult to separate the
role of the biotic and abiotic environments, but recent methodological and data
advances showcased within this Theme Issue offer increased hope for a brighter future
in which we gain a better understanding of how ecological mechanisms regulate the
interplay between organismal biology and environmental change to drive
macroevolutionary dynamics.

**Figure Legends**

**Fig. 1.** Rejection of Van Valen’s law in Cenozoic Era macroperforate planktonic foraminifera [26] depends on the level of biological organisation used in analysis. We define the homogeneous group for analysis by controlling for morphotype (presence/absence of keels, symbionts and spines), depth habitat, changes in overall climate [27, 28] and overall standing diversity. The scale parameter determines the curvature in extinction risk according to the Weibull distribution; a value of 1 reduces the Weibull to its simpler exponential distribution of constant extinction risk.

**Fig. 2.** Simplified schematic of the main regulators of biodiversity in deep time for a given clade. We do not indicate the impacts of space in the schematic because it is assumed that if species are interacting, then, to some extent, their ranges must overlap.
Coloured boxes denote distinct ecological types, which compete amongst each other and respond differentially to the same biotic and abiotic signals.

**Fig. 3.** Diversity-dependent controls acts more strongly through speciation than extinction in Cenozoic Era planktonic foraminifera [26] and Canidae over the last 40 Myr [45]. Number of species was calculated at the start of each bin and regressed against speciation or extinction rate in the next 1 Myr. Regression lines correct for overdispersion and non-constant variance with the mean. Solid lines indicate statistically significant relationships (p < 0.01) while dashed lines indicate non-significant (p > 0.05) relationships.
