

Global genomic similarity and core genome
sequence diversity of the *Streptococcus* genus as
a toolkit to identify closely related bacterial species
in complex environments.

Abstract

Background. Comparative genomics between closely related bacterial strains can distinguish important features determining pathogenesis, antibiotic resistance, and phylogenetic structure. The *Streptococcus* genus is relevant to public health and food safety and it is well-represented (>100 genomes) in databases of publicly available databases. Streptococci are cosmopolitan, with multiple sources of isolation, from humans to dairy products. The *Streptococcus* genus has been classified by morphology, serotypes, 16S rRNA gene, and Multi Locus Sequence Types (MLST). The Genomic Similarity Score (GSS) is proposed as a tool to quantify genome level relatedness between species of *Streptococcus*. The *Streptococcus* core genome can be used to assess strain specific abundances in metagenomic sequences.

Methods. A 16S rRNA gene phylogeny was calculated for 108 strains, belonging to 16 *Streptococcus* species and compared to a dendrogram using GSS pairwise distances for the same genomes. The core and pan-genome were calculated for these 108 genomes. The core genome sequences were analyzed and used as a resource to discriminate homologous fragment reads from closely related strains in metagenomic samples.

Results. A total of 404 proteins are shared by all 108 *Streptococcus* genomes, which is the core genome. The pairwise amino acid identity values of the core proteins for all the compared strains and outgroups are reported. Lower sequence identity variation (90-100%) is predominantly found in core clusters containing ribosomal and translation-related proteins. For 48 core proteins (11.8%) no functional assignment could be made and those proteins have larger sequence identity variations than other core proteins. The sequence identity of the core genome diminishes as GSS score between species decreases. The GSS dendrogram recovers most of the clades in the 16S rRNA gene phylogeny while distinguishing between 16S polytomies (unresolved nodes). Finally, the core genome was used to distinguish between closely related species within human oral

metagenomes.

Discussion. The *Streptococcus* genus provides a benchmark dataset for comparative genomic studies due to the breath depth of genomic coverage. Comparing metagenomic shotgun fragment reads to the core genome using rapid
50 alignment tools allows species-specific abundance estimates in metagenomic samples. Understanding of genomic variability and strains relatedness is the goal of tools like GSS, which make use of both pairwise shared core and pan-genomic homologous shared sequences for its calculation.

Background

55 *Streptococcus* is a bacterial genus that encompasses more than 40 different species, from a diverse range of human and animal pathogens like the etiological agents for caries and meningitis, to commensal species inhabiting animal guts and respiratory tracts (Kilian, 2012). Classification within the genus has been done by morphology, biochemical profiles, serum types, and more recently using the
60 comparison of 16S ribosomal RNA (rRNA) gene phylogenies (Kawamura et al., 1995). There are also Multi Locus Sequence Types (MLST) for eight streptococci species (Kawamura et al., 1995). The Streptococci are divided into six main paraphyletic groups, because of clinical or practical ease, named: *pyogenes*, *mitis*, *anginosus*, *salivarius*, *bovis*, and *mutans* according to the representative species for
65 each clade (Kilian et al., 2008). There are multiple genome sequences available for the Streptococci; most of the species used in this work were isolated from humans, bovine, swine, and dairy product samples (Supplemental Information 1).

Bacterial phylogenetics has been done using multiple criteria to define bacteria species. The current standards are based either on genome wide Average
70 Nucleotide Identity (ANI) above 95% for estimating an overall genome related index (OGRI) (Konstantinidis & Tiedje, 2005; Konstantinidis, Ramette & Tiedje, 2006; Chun et al., 2018) or on 16S rRNA gene sequence comparison with a 97% identity or above the threshold to identify a bacterium species (Stackebrandt & Goebel, 1994). Protein translation is universal to cellular life, and thus the conservation of the
75 molecular-associated machinery has been used as a molecular taxonomic marker due to its high conservation across the tree of life, including the 16S rRNA gene. However, 16S rRNA has a slow evolutionary rate which does not allow enough resolution to distinguish between closely related species (Stackebrandt & Goebel, 1994). The use of multiple coding genes alignments known as multi locus sequence
80 typing (MLST) is standard practice for distinguishing between strains of pathogenic bacteria. Even what should define a bacterial species based on molecular phylogenetics is fuzzy (Fraser et al., 2009).

The astounding amount of available bacterial genomes (77,107 in GenBank, February 2018); (Liolios *et al.*, 2010) allows genomic phylogenetic reconstructions
85 based on the pan-genome (Tettelin *et al.*, 2005). The core genome for a set of related genomes is a concept that involves the identification of orthologous genes common to a species (Goodall *et al.*, 2017), and even genus (Alcaraz *et al.*, 2010). The biological relevance of the core genome is to be discussed and analyzed yet because it tends to decrease if more genomes are added to the comparison.
90 However, it provides a set of genes that are probably responsible for a genus evolutionary cohesion. For example, 20 strains encompassing 13 species of the *Bacillus* genus were determined to share 814 core genes which defined genus features like the ability to form endospores (Alcaraz *et al.*, 2010).

The core genome is automatically computable by software pipelines that identify
95 shared orthologous genes (Contreras-Moreira & Vinuesa, 2013). Traditional phylogenetic reconstructions only use vertically inherited core genes ignoring clade-specific genes. Ignoring these genes discards relevant elements of the biology of these organisms like horizontal gene transfer (HGT), gene family expansions, and gene content variability. Innocuous and pathogenic strains can be indistinguishable
100 using traditional phylogenetic methods. We think that a metric representing actual genomic distances from pairwise shared homologous genes within a set of bacterial genomes will answer the most common question when sequencing the genome of a new strain: How related is the strain to known relatives?

The Genomic Similarity Score (GSS) has been used to obtain a non-redundant set of
105 genomes (Janga & Moreno-Hagelsieb, 2004; Moreno-Hagelsieb & Janga, 2007; Alcaraz *et al.*, 2010; Moreno-Hagelsieb *et al.*, 2013). The GSS is a pairwise metric that depends on the normalized bit-scores of reciprocal best BLAST hits between orthologous proteins. GSS takes values from 0 to 1: when all orthologous proteins between two proteomes are identical it has a maximum value of 1, two genomes with
110 no orthologous proteins have a value of 0 (Moreno-Hagelsieb & Janga, 2007). Best reciprocal BLAST hits have been used to identify orthologs when comparing complete genomes (Moreno-Hagelsieb & Janga, 2007). The pairwise GSS values can define a distance matrix between a set of genomes which can be turned into a distance dendrogram. Outgroups can be included in the comparison to root the

115 dendrogram.

The GSS score was used to generate a dendrogram for the 108 strains comprising 16 species of *Streptococcus* for comparison to a 16S rRNA gene phylogenetic reconstruction. A core genome was built from the 108 strains to measure the sequence diversity of *Streptococcus*. Additionally, the core genome was used to
120 discriminate between closely related strains in metagenomic sequences of *Streptococcus* dominated environments like the human mouth, where strains of the same genus are differential for causing caries (Belda-Ferre *et al.*, 2012; Alcaraz *et al.*, 2012; López-López *et al.*, 2017).

Methods

125 Analyzed genomes and ortholog mapping.

Predicted proteomes for 108 strains of *Streptococcus*, representing 16 different species were downloaded from NCBI Genbank (Supplemental Information 1). Orthologs were defined as Reciprocal Best Hits (RBH) of pairwise comparisons using the BLASTp program (Camacho *et al.*, 2009), the following parameters were
130 used as previously suggested (Moreno-Hagelsieb & Latimer, 2008): e-value cutoff set to 1e-6 '-evalue 1e-6', mask low complexity regions of the query sequence only during the search phase '-soft_masking "true"', and perform an alignment with the Smith-Waterman algorithm to compute the bitscore '-use_sw_tback'. Then, hits with an alignment length shorter than 60% of the length of the query sequence were
135 discarded. Detailed scripting procedure of RBH is available (Supplemental Information 2).

Genomic Similarity Score (GSS)

The GSS was calculated as previously reported (Janga & Moreno-Hagelsieb, 2004; Moreno-Hagelsieb & Janga, 2007; Alcaraz *et al.*, 2010; Moreno-Hagelsieb *et al.*,
140 2013). Briefly, from the RBH of pairwise comparisons of predicted proteomes, the raw bit-score was parsed for each pair of aligned sequences of the proteomes and summed, then the self-scores of proteome a were summed and used to normalize

the summed raw scores. Values of GSS have a range from 0-1, and GSS formula is calculated in the following form:

$$GSS_a = \frac{\sum_{i=1}^n compScore_i}{\sum_{i=1}^n selfScore_i}$$

145 Where *compScore* is the bitscore of protein *i* against its reciprocal best hit and
selfScore is the bitscore of the alignment of protein *i* against itself in proteome *a*.
Since *selfScore* might differ in proteome *a* and *b*, the final GSS for the proteome pair
ab is the arithmetic mean of GSS_a and GSS_b . We used two bacilli species (*Bacillus*
subtilis 168, and *B. licheniformis*) as outgroups for the comparisons of GSS values,
150 as *Bacillus* is the external group to *Streptococcus* according to a whole genome
phylogeny (Ciccarelli, 2006). An inverse (1-GSS) distance matrix was built and used
to compute a Neighbor-Joining tree using the ape library v. 3.5 (Paradis, Claude &
Strimmer, 2004) for R v. 3.3.1 (R Development Core Team, 2003). A control
phylogeny was built using 16S rRNA full-length sequence from each of the 108
155 streptococci genomes. The multiple alignment for the 16S rRNA genes was done
using structural RNA information using the software ssu-align (v0.1) (Nawrocki,
2009). The resulting 16S rRNA phylogeny was plotted using the Neighbor-Joining
method from MEGA 5.2 (Tamura *et al.*, 2013). GSS calculation protocols are
available as Supplemental Information 2.

160 Core genome calculations

As a reference for all the core genome comparisons the smallest predicted proteome
of all the streptococci analyzed strains was used: *S. agalactiae* 2-22 (FO393392;
1548 proteins). From the RBH calculations, results were compared, and the
intersection set of orthologous proteins for all the 108 streptococci was defined as
165 the core genome. From the local alignments from RBH comparisons, global
alignments were performed using the Needleman-Wunsch method implemented in
needleall of the EMBOSS suite (Rice, Longden & Bleasby, 2000), global alignments
were used to calculate global sequence identity for each core protein. Additionally,

the core genome was defined using the software package GET_HOMOLOGUES
170 (Contreras-Moreira & Vinuesa, 2013) with the blastp program to perform
comparisons and the BDBH algorithm to define orthologous clusters. The minimum
alignment coverage was set to 60% and the maximum E-value to 1e-06. Only
clusters that included at least one sequence from all the analyzed genomes were
considered for further analysis. Only protein coding genes were considered.

175 Pan-genome calculation

The *Streptococcus* genus pan-genome was calculated by clustering all the predicted
proteomes using cd-hit (Huang *et al.*, 2010) with an identity cut-off value of 70%.
This clustering method allows to generate protein family without constraints of
inparalog groupings that collapses large gene family (*i.e.*, ABC transporters).
180 Additionally, GET_HOMOLOGUES was used as a second method to obtain the
genus pan-genome. BLASTp (Camacho *et al.*, 2009) hits with at least 70%
sequence identity, a minimum of 75% alignment length coverage, and an E-value of
1e-6 were considered. The OrthoMCL algorithm (Li, Stoeckert & Roos, 2003) was
used to group sequences. Only protein coding genes were considered.

185 ANI calculation

Average Nucleotide Identity (ANI) was calculated using pyani (Marçais *et al.*, 2018)
for the 108 genomes used in this study (Supplemental Information 1) with two
methods: Mummer (Marçais *et al.*, 2018) using minimum lengths of exact match (20
nt), maximum gaps (90 nt); and BLASTN+ (Camacho *et al.*, 2009) with 1020
190 nucleotide windows.

Core genome and pan-genome annotation

The core and pan-genomes were annotated using MG-RAST (Huang *et al.*, 2010;
Meyer *et al.*, 2017) and their M5NR database (Wilke *et al.*, 2012). Annotation
required a minimum alignment length of 15 amino acids and 60% identity.

195 Streptococci coding genes were uploaded to MG-RAST because it is possible to compare them with multiple metagenomes, in particular, human oral metagenomes where *Streptococcus* species composition has repercussions for health or disease status (Belda-Ferre *et al.*, 2012; Alcaraz *et al.*, 2012; López-López *et al.*, 2017).

Metagenomic comparisons

200 Fragment recruitment analysis (Rusch *et al.*, 2007) was done to compare oral metagenomes from a healthy and diseased individuals against the *Streptococcus* reference core genome for each streptococci species using Nucmer from the Mummer suite (Marçais *et al.*, 2018). A cut-off value of 90% identity (nucleotide) was chosen for classifying each metagenomic read to an individual species. Using
205 minimum lengths of exact match (20 nt) and maximum gaps (90 nt).

Results

Phylogenetic and genome similarity of the *Streptococcus* genus.

A 16S rRNA phylogenetic reconstruction was done as a reference and confirms previously proposed clades (Fig. 1A) (Kawamura *et al.*, 1995). There is a Pyogenic
210 clade containing multiple species: *S. pyogenes*, *S. dysgalactiae*, *S. equi*, *S. uberis*, *S. parauberis*, *S. agalactiae*, and *S. pneumoniae*. A second clade is the Salivarius group formed just by *S. thermophilus* and *S. salivarius*. The Mutans clade groups the following species: *S. mutans*, *S. infantarius*, *S. lutetiensis*, *S. macedonicus*, and *S. gallolyticus*. The species *S. suis* has its clade with multiple strains of the same
215 species. A fifth clade known as Mitis group is the basal group: *S. pneumoniae*, *S. pseudopneumoniae*, *S. mitis*, *S. pasteurianus*, *S. parasanguinis*, *S. sanguinis*, *S. gordonii*, *S. oligofermentans*, and *S. intermedius*. The external groups are *Bacillus subtilis* 168 and *B. licheniformis*.

Besides, ANI was calculated for all the Streptococci genomes. ANI was able to
220 discriminate main Pyogenic and Suis clades (Fig. 1 B); but it does break Mutans, Salivarius, which are supported both by 16S phylogeny and GSS dendrogram (Fig. 1 A,C). Interestingly, there is an ANI clade formed by a mix of Pyogenic, Mitis, and

Salivarius groups, not supported neither by GSS or 16S phylogeny. ANI correlogram is available (Supplemental Information 3).

225 The GSS dendrogram has the same clades as the 16S rRNA (Fig. 1C); however, GSS rearranges the Pyogenic group, where *S. agalactiae* is included interior to the Pyogenic clade in the 16S phylogeny, GSS shows it as the basal group for the Pyogenic clade. Another rearrangement of GSS has the Suis group as a sister clade to the Mitis group, but in the 16S rRNA phylogeny, Suis is placed as a sister clade to the Pyogenic group. It is noticeable that the GSS dendrogram distances are large
230 enough to distinguish discrete groups among closely related strains like such as the inner clades of Suis, Pyogenic, Mutans, and Mitis groups. Resolved clades are formed in the GSS dendrogram for strains of *S. pneumoniae* and *S. pseudopneumoniae*; whereas, 16S rRNA does not distinguish inner relationships,
235 but rather allows polytomies. Also, the Suis GSS clade shows clearly resolved branches when comparing to the 16S rRNA phylogeny.

Core genome sequence diversity

According to the RBH method, the 108 streptococci core genome has 404 proteins is a small number compared to the average protein content of 1,929 for the 108
240 strains. The core proteins represent one-fifth of the average predicted proteome. The total pan-genome comprises 33,039 protein clusters (families) at 70% identity (Supplemental Information 4). According to the GET_HOMOLOGUES method, the core genome is composed of 306 proteins and the pan-genome of 36,387. Comparisons of the core proteins obtained by both methods find 255 proteins, the
245 RBH method finds 149 unique proteins, while GET_HOMOLOGUES finds only 51 unique proteins (Supplementary Information 5).

Paired global alignments were performed to analyze variation across species and strains over the core genome (Fig. 2). For each core cluster, the individual proteins were plotted showing the pairwise identity of the protein compared to a reference
250 sequence from *S. pyogenes* which was chosen as the reference because of its top phylogenetic position both in 16S and in GSS dendrogram (Fig. 2). The high sequence identity (mean=77.6±11.5) for the core proteome is suggesting evidence

for selective constraints (Supplemental Information 5). Identity to *S. pyogenes* over the core genome, diminishes as the genomic distances to other species increase.

255 The range of protein sequence diversity in the core proteome goes from 25 - 100% identity. Based on the core proteome sequence diversity, we were able to describe a set of phylogenetic markers that can be used as DNA references to identify and discriminate between closely related species in metagenomes using high nucleotide identity cut-offs (>90%). Core genes for each of the streptococci species described

260 here are available for the community in FASTA format (Supplemental Information 6).

Core genome functional analysis

Normalized abundances (Z-scores) of the pan-genome against the core were compared to stress out the over-represented protein categories in the core (Fig. 3). The most abundant genes in the 404 protein core clusters are related to the

265 translational machinery, including ribosomal proteins and translation-related proteins (Z=3.08 core; Z=0.88 pan-genome). There are more cell division related proteins in the core genome (Z=-0.87), than in the pan-genome (Z=-1.06). Membrane and cell envelope coding genes (M) are better represented in the core genome (Z=0.22; Z=0.10 pan-genome). The most conserved core proteins (average pairwise identity

270 >90%) are mostly related to the translation process, and the top 10 are exclusively ribosomal proteins (Supplemental Information 5). As average pairwise identity decreases for the core proteins, several transport proteins appear along with multiple transport-related proteins, transcriptional regulators, phosphatases, recombinases, peptidases, multidrug and efflux transporters (MATE), and hypothetical proteins (Fig.

275 2; Supplemental Information 5). There is also a high proportion of core proteins with unknown function (48 out of 404; 11.81%).

Using the core genome to scan oral metagenomes

Metagenomic shotgun reads from oral microbiome samples were mapped to the individual sequences from the core genome to estimate relative abundance for each

280 *Streptococcus* species. Oral metagenomes were chosen because of the many streptococci with high abundance (4 to >20%) (Supplemental Information 7). Two oral metagenomes were chosen: a patient with active caries and a healthy adult that

never suffered from caries (Belda-Ferre *et al.*, 2012). In both metagenomes, the species with the most recruited number of fragments was *S. pneumoniae* (Fig. 4 and
285 Table 1), but the caries etiological agent *S. mutans* is depleted (17 metagenomic fragments) in the caries-free individual (NOCA_01) and abundant (127 metagenomic fragments) in the patient with caries. Recruiting metagenomic sequences against each reference core genome and filtering alignments with high identity levels ($\geq 90\%$) shows that is possible to generate species-specific profiles
290 (Fig. 4, Table 1).

Discussion

Streptococcus species have historically been classified by their cell wall antigenic properties (Kayser, Bienz & Eckert, 2011) and clinical criteria for pathogenic strains like hemolysis capabilities. More recently molecular phylogenetics has aided
295 streptococci classification (Kawamura *et al.*, 1995; Kilian *et al.*, 2008). Analysis of genomic variability within the same species expanded with the definition of relevant concepts like the pan-genome and the core genome for *S. agalactiae* (Tettelin *et al.*, 2005).

The core genome is dependent on the set of genomes being analyzed, for each
300 genome added the size of the core would decrease if any genes are not present for that genome. Besides this, different methods can estimate different core and pan-genome sizes, this have been shown in previous works (Fouts *et al.*, 2012). In this work, 404 core proteins comprise the core genome according to the RBH method and given the 108 strains compared, while GET_HOMOLOGUES gets 306 proteins.
305 Historically, the first core genome for streptococci was 611 genes for 26 genomes (Lefébure & Stanhope, 2007); a second effort wast 547 genes for 64 genomes (Van den Bogert *et al.*, 2013); a third reconstruction gave 369 core genes for 138 strains (Gao *et al.*, 2014). Interestingly, 11.81% of the core genes of streptococci are of unknown function (Supplemental Information 5), representing an opportunity as
310 possible therapeutic targets.

The core genome for streptococci provides a platform for investigating what is

essential to the lifestyle of these organisms and also can be used to analyze their presence in metagenomic samples. Additionally, we think that traditional phylogenetic methodology is necessary to understand vertical group evolution and

315 GSS or similar measures of whole genome relatedness are an improvement over marker gene-based methods. However, bacteria have amazing capabilities to transfer genes through conjugation, transformation, and competence, with high rates of recombination, which pose a challenge for traditional phylogenetics (Frost *et al.*, 2005; Francino, 2012). Pan-genomic analysis shows the variability within a species

320 which may indicate adaptation to particular environments through additions or deletions to the genomic repertoire (Tettelin *et al.*, 2008; Mira *et al.*, 2010; Vernikos *et al.*, 2015). The GSS measures bacterial strain similarity over all homologous genetic elements shared by a pair of bacteria, no matter if it is vertically or horizontally transmitted (Janga & Moreno-Hagelsieb, 2004; Moreno-Hagelsieb &

325 Janga, 2007; Alcaraz *et al.*, 2010; Moreno-Hagelsieb *et al.*, 2013). Recently, new standards are establishing in the bacterial taxonomic rules trying to make use of whole genome information, and ANI is the preferred choice to discriminate between species (Chun *et al.*, 2018). Working at with genus level, involves methods able to identify homologous sequences, here we found protein sequence diversity with

330 distances spanning from 100% to less than 25% identity for the global alignments. The main advantage of GSS is that it uses both core and pan-genomic information to estimate relatedness between strains. Proteins are the choice to find homologs with large evolutionary distances (Rost, 1999). ANI will be the choice when comparing inside strains of the same species (Chun *et al.*, 2018), but it discards homologous

335 information due to the shortcome of comparing nucleotides when comparing long time diverging lineages, in Streptococci there are estimates about 0.5 billion years of the last common ancestor (Battistuzzi, Feijao & Hedges, 2004). Multiple sequenced strains redundancy complicates comparative genome analysis, information beyond nucleotide clustering is needed; genome redundancy elimination by using

340 information like distance matrix or phylogenetic information like GGRaSP (Clarke *et al.*, 2018), GSS could easily integrate to tools like GGRaSP.

The GSS dendrogram is consistent with the accepted clades of streptococci. GSS provides better resolution of clade structure and distances than the 16S rRNA gene based phylogeny (Fig. 1). Within group resolution is greatly improved in the GSS

345 dendrogram for several streptococci species like *S. pyogenes*, *S. suis*, *S. mutans*,
and *S. pneumoniae* which are practically indistinguishable using 16S but GSS shows
monophyletic clades for each species with clear branching and long enough
distances to identify each strain within a species (Fig 1C).

The growth of metagenomic data needs a framework to distinguish between closely
350 related strains. Some environments host intra-genus diversity with implications for
health like human vaginal microbiomes dominated by *Lactobacillus* species (Gajer *et al.*,
et al., 2012), and the human oral microbiome (Belda-Ferre *et al.*, 2012; Simón-Soro *et al.*,
et al., 2013). There are multiple ways to bin metagenomic diversity from nucleotide k-
mer frequencies (Ulyantsev *et al.*, 2016), using phylogenomic markers (Segata *et al.*,
355 2012), AMPHORA (Segata *et al.*, 2012; Kerepesi, Bánky & Grolmusz, 2014), through
annotation of ribosomal genes (Pruesse *et al.*, 2007; Cardenas *et al.*, 2009), and
lowest common ancestor binning (Huson *et al.*, 2007; Meyer *et al.*, 2017). In this
work, the use of the core genome of a genus provides a relatively simple (404
genes) dataset to align metagenomic information (reads, contigs) against and
360 estimate species abundances based on the coverage and identity of each aligned
fragment (Fig. 4). Despite the biological relevance, or connecting it to essential
genes (Goodall *et al.*, 2017), the core genome of a clade provides a resource to
discriminate between closely related strains. Sequence identity variation within the
core genome provides a basis for understanding the differential selective pressure
365 for each core cluster (Supplemental information 5). Core genome variation could be
exploited in practical and biological meaningful ways like probe and diagnosis design
or understanding conserved but highly variable proteins.

Conclusions

The core genome of bacteria, no matter if species, genus or whatever preferred level
370 should be an open repository and recalculated each time a new strain is sequenced,
and shared with the scientific community, maybe through a “living” paper that self-
updates with new genomes. Here is presented a working version of streptococci core
genome with 404 predicted proteins. Additionally, core genome and pan-genome are
not just mathematical concepts only, the functional metabolic roles of the known
375 genes are relevant and also its natural variations. Traditional marker gene based

phylogenetic tools in bacteria are invaluable; however, they do not capture the dynamism occurring in bacterial genomes and other tools like the GSS better distinguish genome level relatedness between species. A practical use for the core genome of the streptococci is to classify abundances of different species and strains
380 in metagenomic samples. Finally, the range of sequence diversity within each *Streptococcus* core cluster will need further analysis to determine if the level of sequence identity correlates with selective pressures.

Acknowledgements

We are grateful to the Facultad de Ciencias UNAM community for their warm and
385 sincere welcoming and giving us the opportunity to do our research with them, particularly to Víctor Valdés-López, Luisa A. Alba-Lois, Claudia Segal, and Viviana Escobar for their helpful support that made this work possible. The authors sincerely appreciate Granger Sutton reviewer work whose suggestions significantly improve our manuscript, along with the comments of other two anonymous reviewers.

390 Funding

HBT, MR, and SMS had fellowships from CONACyT. LDA got funding from DGAPA-PAPIIT-UNAM TA2001171 and SEP-CONACyT Ciencia Básica 237387.
