Background. Copepods are the major secondary producers in the World Ocean. They represent an important link between phytoplankton, microzooplankton and higher trophic levels such as fish. They are an important source of food for many fish species, but also a significant producer of detritus. In terms of their role in the marine food web, it is important to know how the environmental variability affects the population of Copepoda.

Methods. The study of the zooplankton community in the south-western Baltic Sea conducted during a 24-month survey (January 2010 to November 2011) resulted in 24 invertebrate species identified (10 copepods, 7 cladocerans, 4 rotifers, 1 ctenophore, *Fritillaria borealis* and *Hyperia galba*). Data were collected at two stations located on the open-sea deep-water station – the Gdańsk Deep (54°50'φN, 19°19'λE) and in the western, inner part of the Gulf of Gdańsk (54°32' φN, 18°48.2 'λE). Vertical hauls were carried out using two nets: a Copenhagen net with an inlet diameter of 50 cm and a mesh diameter of 100 μm (in 2010) and WP-2 net from KC Denmark with an inlet diameter of 57 cm and a mesh diameter of 100 μm (in 2011).

Results. The paper describes seasonal changes in the abundance and biomass of Copepoda, taking into account the main Baltic calanoid copepod taxa (*Acartia* spp., *Temora longicornis* and *Pseudocalanus* sp.). They usually represented the main component of zooplankton. The average number of Copepoda at station P1 during the study period of 2010 was 3913 ind.m⁻³ (SD 2572) and their number ranged from 1184 ind. m⁻³ (in winter) to 6293 ind.m⁻³ (in spring). One year later, the average count of copepods was higher, i.e. 11 723 ind. m⁻³ (SD 6980) and ranged from 2351 ind. m⁻³ (in winter) to 18 307 ind.m⁻³ (in summer). Their average count at station P2 in 2010 was 29 141 ind. m⁻³ ranging from 3330 ind.m⁻³ (in March) to 67 789 ind. m⁻³ (in May). The average count of copepods in 2011 was much lower – 17 883 ind./m³ and ranged from 1360 ind./m³ (in April) to 39 559 ind./m³ (in May).

Discussion. The environment of pelagic animals changes with the distance from the shore and with the sea depth. Although the qualitative structure of zooplankton is almost identical with that of the coastal waters, the quantitative structure changes quite significantly. The maximum values of zooplankton abundance and biomass were observed in the summer season, both in the Gdańsk Deep and the inner part of the Gulf of Gdańsk. Copepoda dominated in the composition of zooplankton for almost the entire duration of the research.. Quantitative taxonomic composition of Copepoda at station P1 (the Gdańsk Deep) was different compared to station P2 (the western, inner part of the Gulf of Gdańsk) due to a high percentage of a crustacean preferring waters with lower temperature and higher salinity – *Pseudocalanus* sp.

24 **Abstract**

25 **Background.** Copepods are the major secondary producers in the World Ocean. They represent
26 an important link between phytoplankton, microzooplankton and higher trophic levels such as
27 fish. They are an important source of food for many fish species, but also a significant producer
28 of detritus. In terms of their role in the marine food web, it is important to know how the
29 environmental variability affects the population of Copepod.

30 **Methods.** The study of the zooplankton community in the south-western Baltic Sea conducted
31 during a 24-month survey (January 2010 to November 2011) resulted in 24 invertebrate species
32 identified (10 copepods, 7 cladocerans, 4 rotifers, 1 ctenophore, *Fritillaria borealis* and *Hyperia*
33 *galba*). Data were collected at two stations located on the open-sea deep-water station – the
34 Gdańsk Deep (54°50'φN, 19°19'λE) and in the western, inner part of the Gulf of Gdańsk (54°32'
35 φN, 18°48.2' λE). Vertical hauls were carried out using two nets: a Copenhagen net with an inlet
36 diameter of 50 cm and a mesh diameter of 100 μm (in 2010) and WP-2 net from KC Denmark
37 with an inlet diameter of 57 cm and a mesh diameter of 100 μm (in 2011).

38 **Results.** The paper describes seasonal changes in the abundance and biomass of Copepod, taking
39 into account the main Baltic calanoid copepod taxa (*Acartia* spp., *Temora longicornis* and
40 *Pseudocalanus* sp.). They usually represented the main component of zooplankton.

41 The average number of Copepod at station P1 during the study period of 2010 was 3913 ind. m⁻³
42 (SD 2572) and their number ranged from 1184 ind. m⁻³ (in winter) to 6293 ind. m⁻³ (in spring).

43 One year later, the average count of copepods was higher, i.e. 11 723 ind. m⁻³ (SD 6980) and
44 ranged from 2351 ind. m⁻³ (in winter) to 18 307 ind. m⁻³ (in summer).

45 Their average count at station P2 in 2010 was 29 141 ind. m⁻³ ranging from 3330 ind. m⁻³ (in
46 March) to 67 789 ind. m⁻³ (in May). The average count of copepods in 2011 was much lower –
47 17 883 ind./m³ and ranged from 1360 ind./m³ (in April) to 39 559 ind./m³ (in May).

48 **Discussion.** The environment of pelagic animals changes with the distance from the shore and
49 with the sea depth. Although the qualitative structure of zooplankton is almost identical with that
50 of the coastal waters, the quantitative structure changes quite significantly. The maximum values
51 of zooplankton abundance and biomass were observed in the summer season, both in the Gdańsk
52 Deep and the inner part of the Gulf of Gdańsk. Copepod dominated in the composition of
53 zooplankton for almost the entire duration of the research.. Quantitative taxonomic composition
54 of Copepod at station P1 (the Gdańsk Deep) was different compared to station P2 (the western,

55 inner part of the Gulf of Gdańsk) due to a high percentage of a crustacean preferring waters with
56 lower temperature and higher salinity – *Pseudocalanus* sp.

58 **Introduction**

59 The Baltic is a shallow, shelf sea from the group of internal (intracontinental) seas. It is the
60 youngest European sea and one of the youngest seas of the Atlantic Ocean. It covers an area of
61 ca. 415 000 km². It is connected with the North Sea through a number of straits: the Danish
62 Straits (Sund, Little Belt and Great Belt), Kattegat and Skagerrak. The generally accepted
63 division of the Baltic Sea, based on the seabed topography, enables the identification of regions
64 with clearly defined hydrographic parameters (Fonselius, 1969; Omstedt, 1990), i.e. the Gulf of
65 Bothnia, the Bothnian Sea, the Gulf of Finland, the Gulf of Riga, the Baltic Proper (the southern
66 Baltic), the Danish Straits and Kattegat.

67 The Baltic waters are characterized by fluctuations in salinity resulting from, inter alia, irregular
68 inflows of fresh waters and inflows from the North Sea. This phenomenon occurs mainly in the
69 Danish Straits and estuaries, and contributes to the two-layer structure of the Baltic waters
70 (Matthäus & Franck, 1992; Fonselius & Valderrama, 2003; Leppärant & Myrberg, 2009). The
71 upper layer consists of lighter waters with salinity ranging from 20 PSU in the Kattegat to 2-
72 3 PSU at the northern end of the Gulf of Bothnia and the eastern end of the Gulf of Finland, and
73 8 PSU in the Baltic Proper. Surface waters are well mixed and oxygenated, and their
74 temperature varies depending on the season from 0°C to 20°C. The lower, deepwater zone is
75 characterized by basically constant temperature of 4-6°C and higher salinity ranging from 12 to
76 20 PSU depending on the region. Stability between these zones is attributed to the halocline,
77 which separates the surface waters from the deepwater layer preventing mixing of the waters, in
78 particular at the open sea. The Southern Baltic is an area of particular importance to the entire
79 Baltic Sea. Saline waters from the North Sea are passing through this region of the Baltic. The
80 direction of the near-bottom flows is affected by the seabed topography. The Słupsk Furrow,
81 with the maximum depth of 92 m and the width of 40 km, is a gateway through which inflow
82 waters move eastwards from the North Sea. Water inflows from the North Sea raises the Baltic
83 water salinity. The oxygen content and the dynamics of temperature are determined by the

84 seasons. Although the Gdańsk Deep is located off the inflow-water transit axis, it plays an
85 important role in this process (Osiński, 2009).

86 Zooplankton of the Baltic Sea consists of both unicellular (protozooplankton) and multicellular
87 organisms of the complex structure (metazooplankton). Mesozooplankton is the dominant group
88 of organisms in the Baltic Sea in terms of biomass (Möllmann, Kornilovs & Sidrevics, 2000;
89 Dzierzbicka-Glowacka, Bielecka & Mudrak, 2006; Dzierzbicka-Glowacka et al., 2012;
90 Dzierzbicka-Glowacka, Kalarus & Żmijewska, 2013). As reported by the studies conducted in
91 the western part of the Gulf of Gdańsk in 1980 (Wiktor, 1990), it may represent up to 76% of
92 the average annual carbon weight. In terms of biomass and production, Copepod are the most
93 important taxa of zooplankton in the Baltic Sea, e.g. *Pseudocalanus* sp., *Temora longicornis* and
94 *Acartia* spp., while Rotatoria are mainly represented by *Synchaeta* spp. and Cladocera with the
95 dominance of *Evadne nordmanni* (Dzierzbicka-Glowacka et al., 2015). The species
96 *Pleurobrachia pileus* belonging to Ctenophora, the copepod *Eurytemora affinis* and rotifers
97 *Keratella* spp. are the least important taxa in the biomass and production of zooplankton
98 (Wiktor, 1990; Wiktor & Żmijewska, 1996; Mudrak & Żmijewska, 2007). Between the
99 dominant species and those from the end of the scale, there are intermediate species living in the
100 Baltic Sea and characterized by very similar biomass values, e.g. *Flitilaria borealis*
101 (Appendicularia), larvae of Polychaeta and Bivalvia, cladocerans *Bosmina* spp. and *Podon* spp.
102 as well as the copepod *Centropages hamatus* (Andrulewicz et al., 2008).

103 Spatial variation in the species composition of mesozooplankton results primarily from the
104 salinity of the Baltic Sea. The smallest number of species (13-20) occurs in the central region of
105 the Baltic Proper and it increases in marine and freshwater regions. The largest number of
106 species (ca. 28-32) is encountered in the south-western part of the Baltic Proper, which is
107 strongly affected by the North Sea (Andrulewicz et al., 2008).

108 Copepods are one of the most important links in the food web. They play an important role in
109 the transmission of energy between producers and consumers of higher orders, being i.a. food
110 for many pelagic, planktivorous fishes. Copepod are also characterized by varying tolerance to
111 salinity and consequently the presence or absence of specific species enables the determination
112 of physicochemical properties of the environment.

113 The main objective of the study was to describe the seasonal changes in the abundance and
114 biomass of the major Baltic copepod species (*Acartia* spp., *Temora longicornis* and

115 *Pseudocalanus* sp.) in the Gdańsk Basin (the southwestern Baltic Sea) based on the research
116 conducted in 2010-2011 in the Gdańsk Deep and in the western part of Gulf of Gdańsk. The data
117 obtained will be used as a background for future numerical evaluations.

118

119 **Material and methods**

120 Planktonic material, which is the basis of *in situ* studies, was collected in the southern part of the
121 Baltic Sea from two stations: the Gdańsk Deep and the western part of the Gulf of Gdańsk.

122 The first series consists of biological material collected aboard the ship of the Institute of
123 Oceanology of the Polish Academy of Sciences – r/v “Oceans” – during 7 cruises in the area of
124 Gdańsk Deep (54°50'φN, 19°19'λE) (Fig. 1, station P1), in the period from February 2010 to
125 November 2011. The maximum depth of this site is ca. 100 m.

126 Vertical hauls were carried out using two nets: a Copenhagen net with an inlet diameter of 50 cm
127 and a mesh diameter of 100 μm (in 2010) and WP-2 net from KC Denmark with an inlet
128 diameter of 57 cm and a mesh diameter of 100 μm (in 2011).

129 The plankton net mesh size was selected so as to collect the mesozooplankton together with the
130 younger developmental stages of Copepod, i.e. the main object of the study. A flow meter was
131 placed at 1/3 of the diameter of the net inlet to determine the amount of water filtered.

132 The material was collected in accordance with the HELCOM guidelines (Manual for Marine
133 Monitoring in the COMBINE Programme of HELCOM, Annex C-7). Vertical net hauls were
134 carried out in three layers: the bottom – the upper limit of the halocline (with no halocline
135 present – 75 m), the upper limit of the halocline – thermocline (with no thermocline present – 25
136 m), the upper limit of the thermocline – the surface. A total of 21 samples were collected, both
137 during the day and night.

138 Table S1 presents a list of material at P1 station. The division into seasons used in Table S1 and
139 in the following part of the study was adopted on the basis of water temperature.

140 The analyzed material from the Gdańsk Deep was used to determine the composition and
141 seasonal changes in the abundance and biomass related to time and space.

142 The second series of the study material consisted of monthly zooplankton samples collected in
143 the western part of the Gulf of Gdańsk (54°32' φN, 18°48.2 'λE) (Fig. 1, station P2) in the
144 period from 11 February 2010 to 29 November 2011, from aboard the ship of the Institute of
145 Oceanography of the University of Gdańsk – kh “Oceanograf 2”. The site of biological material

146 collection was characterized by a depth of 40 m and was located 9.5 Mm away from the shore.
147 Vertical net hauls were carried out along the water column divided into 10 m thick layers, from
148 the bottom up to the water surface. The exception was the 27th of July 2011 when samples were
149 collected from the following layers: 20-0, 30-20 and 40-30 m, due to equipment failure. In total,
150 71 samples were collected in this series.

151 Table S2 presents a list of material at P2 station.

152 Net hauls were carried out only during the day, using (like in Gdańsk Deep in 2011) a WP-2
153 closing net with an inlet diameter of 57 cm and mesh size of 100 μm . The flow meter was placed
154 at 1/3 of the net inlet diameter to determine the amount of water filtered. The collected material
155 was immediately moved into plastic bottles and treated with 4% solution of formaldehyde to
156 preserve animals for subsequent analysis. A total of 92 samples were analyzed. Biomass was
157 calculated from abundance with weight standards after Hernroth (1985).

158

159 **Results**

160 **Environmental conditions during the study period**

161 Measurements of hydrometeorological conditions, taken during the biological material sampling
162 (from January 2010 to November 2011), represent an environmental description within a specific
163 time and space frame (Data S1).

164 Environmental data for Gdańsk Deep (P1), water temperature and salinity were measured in the
165 whole water column using the STD probe. Measurements were performed during seven cruises
166 aboard the vessel r/v “Oceania” prior to the biological material collection.

167 In February 2010, the water temperature in the surface layer was 1.83°C and it gradually
168 increases with increasing depth, reaching the maximum value of 9.08°C at the bottom. The upper
169 limit of the thermocline was determined at a depth of approximately 60 m. In June 2010, the
170 water temperature was measured only to a depth of 60 m and it ranged from 10.7°C on the
171 surface to ca. 13°C in the deepest layer.

172 The temperature of surface waters in March 2011 was much lower compared to February 2010,
173 i.e. 1.39°C and remained constant to a depth of ca. 65 m, i.e. the upper limit of the thermocline.

174 Below this depth, the temperature significantly increases, reaching the value of 6.19°C at the
175 bottom. In June 2011, the water temperature was measured only to a depth of ca. 50 m. The
176 temperature drops with increasing depth, from 15.18°C at the surface to 6.38°C at a depth of

177 50 m. November 2011 was characterized by a high temperature of surface water, i.e. 11.45°C,
178 which remained relatively constant up to a depth of ca. 40 m and rapidly dropped at greater
179 depths. Due to strong waves and surface-water cooling, the thermocline was at a depth of ca. 40-
180 50 m. The water temperature at the bottom was 5.17°C.

181 Salinity of surface waters at station P1 ranged from 7.45 to 6.94 PSU and gradually increased
182 along the depth gradient, reaching the maximum value of 12.55-10.84 PSU at the bottom. In
183 June 2010, the salinity was measured only to a depth of 60 m; it ranged from 7.3 PSU at the
184 surface to 6.2 PSU in the deepest layer. Such a large decline in salinity was probably caused by
185 the inflow of flash flood waves into the Gulf of Gdańsk after a disastrous spring inundation in
186 the Vistula drainage basin. A likely increase followed along with the increasing depth, which is
187 attributed to the impact of oceanic water inflows from the North Sea.

188 Temperature of surface water and salinity measured in 2010 and 2011 at station P1 (based on the
189 example of June) significantly varied during those two years. The runoff of flood waters in May
190 2010 disturbed the thermohaline system in Gdańsk Deep, which was reflected in a warmer layer
191 of less saline water.

192 The environmental data on the western, inner part of the Gulf of Gdańsk (P2) came from direct
193 measurements carried out on board k/h "Oceanograf-2" (16 trips) and "Hestia" (2 trips).

194 Water temperature at station P2 in the western part of the Gulf of Gdańsk was slightly higher for
195 2010 compared to 2011.

196 From January to March, the surface-water temperature (ca. 1°C) was lower than at the bottom. It
197 gradually increased starting from April and eventually was higher at the surface than at the
198 bottom. However, the differences in both cases were below 1°C. This situation lasted until
199 October 2010 and from July 2011 the water temperature began to level off and uniformly
200 fluctuated till the end of the year. In November 2010 and 2011, basically a constant temperature
201 was observed throughout the water column, on average 8.6°C and 7.3°C, respectively. The
202 warmest month in 2010 and 2011 was August (19.4°C and 18°C), whereas the coldest one –
203 January and March (from 1 to 2.1°C).

204 Salinity at station P2 (depth of 40 m) varied to a small extent, both during the year and
205 throughout the water column. Mean values of water salinity in the western part of the Gulf of
206 Gdańsk ranged from 6.68 PSU (in July 2010) to 7.38 PSU (in October 2011). The lowest salinity

207 was recorded in July 2010 (6.4 PSU), which probably resulted from the inflow of Vistula flood
208 waters.

209 **Copepod abundance**

210 **At stations P1**

211 Copepods occurred both in 2010 and 2011; at stations P1 they occurred throughout the study
212 period. They were usually the main component of zooplankton (Data S2).

213 Due to the limited possibility of monthly collections of biological material for the analysis, data
214 collected for selected seasons were interpreted. Nevertheless, they provide a general picture of
215 the situation prevailing at a given time in the pelagic zone.

216 The average number of Copepod during the study period of 2010 was 3913 ind. m⁻³ (SD 2572)
217 and their number ranged from 1184 ind. m⁻³ (in winter) to 6293 ind. m⁻³ (in spring). One year
218 later, the average count of copepods was higher, i.e. 11 723 ind. m⁻³ (SD 6980) and ranged from
219 2351 ind. m⁻³ (in winter) to 18 307 ind. m⁻³ (in summer) (Fig. 2) (Data S2).

220 The maximum number of Copepod in spring 2010 in the surface layer (25-0 m) was 12 545 ind.
221 m⁻³, while in spring 2011 the count of Copepod in the same layer was 2.5 times higher. In the
222 other months, the highest values of the Copepod count were also recorded in the layer between
223 the upper limit of the thermocline to the surface (Data S2).

224 Quantitative taxonomic composition of Copepod at station P1, based on the quantitative
225 contribution of species, was different compared to station P2, which was attributed to the high
226 percentage of a crustacean preferring waters with lower temperature and higher salinity –
227 *Pseudocalanus elongates*.

228 The species was the main component of Copepod in the winter-spring season of 2010 (ca. 50%),
229 while replaced by *Acartia* spp. (40.26%) and *Temora longicornis* (33.31%) in the summer.

230 During this period, *Centropages hamatus* accounted for several percent of Copepod, while
231 *Eurytemora* sp. was insignificant.

232 In 2011, the situation was similar, i.e. *Pseudocalanus* was the main component of Copepod in
233 the winter-spring season (over 50%), while in the summer-autumn season its contribution
234 dropped and was similar to that of *Temora longicornis* – 40% in summer and 35% in autumn.

235 The percentage of the genus *Acartia* in the described seasons ranged from 10 to 30%. The
236 presence of *Centropages hamatus* in this region ranged from a few to several percent, while the
237 count of *Eurytemora* sp. (similarly to the previous year) was insignificant (Fig. 3).

238 At stations P2

239 At station P2, copepods occurred throughout the study period, both in 2010 and 2011. They
240 usually represented the main component of zooplankton. Their average count in 2010 was 29
241 141 ind. m⁻³ (SD 23315), and ranged from 3330 ind. m⁻³ (in March) to 67 789 ind. m⁻³ (in May).

242 The average count of copepods in 2011 was much lower – 17 883 ind./m³ (SD 11407), and
243 ranged from 1360 ind./m³ (in April) to 39 558 ind./m³ (in May) (Fig.4) (Data S3).

244 The maximum count of Copepod in May 2010 was determined in the 10-0 m layer – 161 150
245 ind. m⁻³, while in September 2011 the Copepod abundance in the same layer was over two times
246 lower (70 314 ind. m⁻³) (Data S5).

247 The analysis of seasonal changes in 2010 revealed two peaks in Copepod abundance: the first
248 one in May and the second one in September with abundance of 67 789 ind. m⁻³ and 57 822
249 ind. m⁻³, respectively. In 2011, there were also two abundance peaks, the smaller one in June-
250 July (22 155 ind./m³) and the larger one in September (39 559 ind./m³) (Fig. 4).

251 It appears that the distribution of Copepod in the water column is determined by the preferences
252 of a species dominant at a given time and its developmental stage.

253 In March and June 2010, the largest number of Copepod was observed in the layer of 30-20 m,
254 while in April – in the 20-10 m layer. During the rest of the year, copepods occurred mainly in
255 the surface layer (10-0 m) (Fig. S1). In 2011, the situation was slightly different. In the early
256 spring and autumn, the largest numbers of Copepod were observed in the layer of up to 20 m.
257 Whereas in the summer, they definitely preferred deeper waters (Fig. S2) (Data S5).

258 In 2010, the genus *Acartia* was the main component of Copepod from March to September
259 (ranging from 26.23 to 89.38%), while in October and November – 32% (Fig. 5). (Data S3).

260 *Temora longicornis* was the second most abundant Copepod species – from 6.85% (in July) to
261 44.90% (in November). In October and November, *Temora longicornis* dominated and in May
262 its abundance was only slightly lower compared to *Acartia* spp.

263 The contribution of *Pseudocalanus elongatus* was also relatively significant and ranged from
264 21.16% in March and 29.16% in April. During the rest of the year, it ranged from only 0.07 (in
265 June) to 6.43% (in November).

266 The abundance of *Centropages hamatus*, similarly to *Pseudocalanus*, was higher in spring and
267 autumn and ranged from 11.38% in March to 16-17% in October and November.

268 On the other hand, the contribution of *Eurytemora* sp. did not exceed 1% throughout the study
269 period, except for October 2010 when it reached ca. 7%.

270 In 2011, the genus *Acartia* accounted for the largest contribution in the abundance of Copepod
271 (except for May and June) and it ranged from 15.81% (in May) to 85.25% (in August) (Fig. 6
272)(Data S3).

273 *Temora longicornis* was the dominant species among Copepod in May (77.19%) and June
274 (58.42%). Its contribution in July, October and November was approximately 30%, and in the
275 other months – just several percent.

276 Similarly to the previous year, *Pseudocalanus elongatus* was the most abundant Copepod species
277 in April (23.45%), while in the other months – it accounted for up to 7%.

278 *Centropages hamatus* was a significant component of Copepod, in October (15.16%) and
279 November (16.33%), the same as in the autumn 2010. Its contribution was insignificant for most
280 of the year, ranging from 0.65 (in May) to 5.34% (in September).

281 In 2011, *Eurytemora* sp. was only an accompanying, supplementary species, accounting for up to
282 1.63% (July) of the total count of Copepod.

283 **Copepod biomass**

284 **At stations P1**

285 The average biomass of Copepod in the zooplankton in 2010 at station P1 was about 116.68
286 mg m^{-3} (SD 37.49) and it ranged from 92.19 mg m^{-3} (in summer) to 159.84 mg m^{-3} (in spring),
287 while in 2011 – the average value was 321.26 mg m^{-3} (SD 247.418) and ranged from 103.67
288 mg m^{-3} (in winter) to 676.20 mg m^{-3} (in summer)(Fig.7) (Data S4).

289 The maximum biomass of copepods in spring 2010 was recorded in the surface layer (up to a
290 depth of 25 m) – 83.59 mg m^{-3} , and in summer 2011 in the intermediate layer (from the upper
291 limit of the halocline to the upper limit of the thermocline, i.e. 70-25 m) – 467.07 mg/m^3 (Data
292 S4).

293 Considering the contribution of individual Copepod taxa in the zooplankton biomass at station
294 P1, one can observe a clear dominance of *Pseudocalanus elongatus*, which accounted for about
295 50% of the total Copepod biomass in the winter-spring season of 2010, while in summer 2010 its
296 abundance dropped in favor of *Temora longicornis* and *Acartia* spp. (ca. 40%). The abundance
297 of *Centropages hamatus* also increased in the spring season up to 23.64%.

298 In the winter-spring season of 2011, *Pseudocalanus* sp. represented approximately 60% of the
299 Copepod biomass, while in the summer its contribution dropped to 22.88% and again increased
300 to 47.97% in the autumn. *Temora longicornis* (65.05%) was the main component of the Copepod
301 biomass in the summer. The contribution of other species was negligible: *Acartia* spp. from 8.80
302 to 13.33% and *Centropages hamatus* from 3.22 to 10.24% (Fig. 8) (Data S4).

303 **At stations P2**

304 The average biomass of Copepod at station P2 in 2010 was 151.46 mg m⁻³ (SD 115) and ranged
305 from 33.87 mg m⁻³ (in March) to 390.12 mg m⁻³ (in May). In 2011, the average Copepod biomass
306 was 95.47 mg m⁻³ (SD 52) and ranged from 12.40 mg m⁻³ (in April) to 164.82 mg m⁻³ (in
307 September) (Fig. 9)(Data S3).

308 The maximum biomass of copepods in May 2010 was recorded in the 10-0 m layer – 692.12
309 mg m⁻³ and 403.98 mg m⁻³ in September 2011.

310 When looking into seasonal changes in the Copepod biomass in 2010, it appears that a
311 significant peak occurred in May – 390.12 mg m⁻³ and two smaller peaks in September (186.73
312 mg m⁻³) and November (114.36 mg m⁻³). In 2011, there were two, basically equivalent biomass
313 peaks: in June (143.27 mg m⁻³) and September (164.82 mg m⁻³) (Fig. 9).

314 As in the case of the Copepod count, the distribution of Copepod biomass in the water column is
315 determined by the preferences of a species dominant at a given time and its development stage.

316 In March and June 2010, the largest number of Copepod was observed in the 30-20 m layer,
317 while in April 2010 – in the 20-10 m layer. In the other months, the highest values of biomass
318 were determined in the surface layer (10-0 m) (Fig. S3) (Data S5).

319 In 2011, the biomass values had a similar pattern, except for January and October when the
320 values were slightly higher at the bottom (40-30 m) (Fig. S4) (Data S5).

321 Species from the genus *Acartia* spp. dominated in the biomass of Copepod at station P2 for most
322 of the 2010 season. Their contribution ranged from 18.92% in November to 89.38% in
323 September. In March, April and November, they were replaced by *Temora longicornis*. In
324 October, the biomass of both taxa was at a similar level – ca. 37%.

325 *Temora longicornis* was a subdominant in the biomass of Copepod. Its contribution ranged from
326 9.65% (in September) to 55.69% (in November).

327 As in the case of abundance, a significant percentage of *Pseudocalanus elongatus* in the biomass
328 of copepods was observed only in March (19.63%) and April (15%), while in the remaining
329 months it ranged from only 0.10% (July) to 7.04% (November).

330 *Centropages hamatus* was a constant component of the Copepod biomass, with the highest
331 values recorded in March (20.74%), April (13.49%), June (13.55%), October (16.12%) and
332 November (17.98%). The percentage of *Eurytemora* sp. in the Copepod biomass was usually up
333 to 1%, except for October – 7.05% (Fig. 10) (Data S3).

334 In 2011, the genus *Acartia* represented a significant component of the Copepod biomass with
335 the contribution ranging from 12.87% (in May) to 88.16% (in August).

336 *Temora longicornis*, being an important and constant component in the biomass of copepods,
337 was observed from April to June, and then in November, ranging from 8.05% (in August) to
338 79.87% (in May). In January and November, the biomass values of *Acartia* spp. and *Temora*
339 *longicornis* were similar.

340 The maximum biomass of *Pseudocalanus elongatus* was determined in April – 14.94%, while
341 for the rest of the year the biomass values were small. In 2011, the crustacean *Centropages*
342 *hamatus* was much more important in the biomass of copepods – over 10% in January, July,
343 October and November, and from 0.89% in May to 7.23% in April. *Eurytemora* sp. were of
344 minor significance in the biomass of Copepod, the same way as in the previous year (Fig. 11)
345 (Data S3).

346 Discussion

347 In terms of biomass and abundance, Copepod are the most important zooplankton taxa in the
348 southern Baltic, and they are mainly represented by e.g. *Acartia* spp., *Pseudocalanus elongatus*
349 and *Temora longicornis*, Rotatoria: *Synchaeta* spp. and *Keratella quadrata*, Cladocera: *Evadne*
350 *nordmanni*, *Eubosmina maritima* and *Pleopis polyphaemoides*. Euryhaline freshwater and
351 typically freshwater species are of lesser importance; they occur mainly at the river mouths (e.g.
352 *Eurytemora* sp.).

353 Copepods represent one of the largest groups of secondary producers in the global ocean. They
354 are an important link between phytoplankton, microzooplankton and higher trophic levels such
355 as fish (Longhurst, 1981; Longhurst & Harrison, 1989; Kleppel, Holliday & Pieper, 1991;
356 Kleppel, 1992; Dzierzbicka-Glowacka et al., 2011). They are an important source of food for
357 many fish species, but also a significant producer of detritus. One individual organism can

358 produce 200 portions of fecal matter per day, which is an important source of food for
359 detritivores and is very important in the processes of sedimentation and circulation of biogenic
360 substances.

361 The study presents an analysis of 92 zooplankton samples from Gdańsk Deep (Gdańsk Basin)
362 and from the western part of the Gulf of Gdańsk in terms of composition, abundance and
363 biomass of zooplankton, with particular emphasis on Copepod, as well as the structure of
364 populations of species occurring in large numbers in the southern Baltic, i.e. *Pseudocalanus* sp.,
365 *Acartia* spp. *Temora longicornis* (which will be described in a separate paper) in 2010 and 2011.

366 **Description of the study area**

367 The environment of Gdańsk Basin is determined by a varying volume of river runoff, easy
368 exchange of water with the Baltic Sea, including periodical inflows (infusions) of seawater, and
369 highly variable morphometric conditions.

370 Seasonal temperature changes occurring in the upper water layer result from seasonal variability
371 in meteorological elements. They are affected mainly by vertical processes, in particular the
372 convection and wind mixing as well as the Vistula water inflows into the Gulf of Gdańsk, which
373 raise the water temperature in the spring-summer season and lower it in the autumn-winter
374 season (Cyberski, 1995). The water temperature in the layer above 80 m gradually increases up
375 to the maximum value at the bottom. Due to lack of contact with the atmosphere, deep waters do
376 not exhibit seasonal changes typical of the upper layer, and their temperature depends on
377 temperatures of inflow waters (Majewski, 1990).

378 Distribution of salinity throughout the year in the surface layer of Gdańsk Basin is affected by a
379 varying volume of river waters reaching the Basin and affecting the anemobaric conditions.

380 Salinity shows a clear seasonal variability in the shallow littoral zone. Differences in the vertical
381 stratification of salinity result from interactions between the Vistula waters – reducing the
382 salinity and deep waters – increasing the salinity (Majewski, 1990). Salinity of benthic waters
383 (above 80 m) also depends on the inflows of saline waters from the North Sea.

384 **Taxonomic composition of zooplankton**

385 According to our environmental studies conducted in 2010/2011, zooplankton was represented
386 mainly by organisms that occur in the pelagic zone (holoplankton) – copepods, cladocerans,
387 rotifers and the only representative of Appendicularia occurring in the Baltic Sea – *Fritillaria*
388 *borealis*. Furthermore, eggs and juveniles of unidentified Ctenophora, a few specimens of the

389 species *Hyperia galba*, larvae of the benthic fauna (meroplankton) as well as eggs and fish
390 spawn (ichthyoplankton) were found. The percentage of individual taxa as well as their
391 horizontal and vertical distribution were determined by meteorological and hydrological
392 conditions prevailing at a given time.

393 A total of 24 taxa were identified in the analyzed material, including: 10 Copepod, 4 Rotifera,
394 7 Cladocera, Ctenophora, *Fritillaria borealis* and *Hyperia galba*. In addition, larvae of the
395 benthic fauna were counted (Polychaeta, Bivalvia, Gastropoda and Cirripedia). They were not
396 identified to the species level, but generally defined as meroplankton. Ichthyoplankton was not
397 analyzed in detail.

398 The research showed that the taxonomic composition of holoplankton in the Gulf of Gdańsk was
399 similar to that observed in this region for many years. The exceptions are two invasive species of
400 Cladocera, which occurred in summer 2010 in the shallow part of the Gulf of Gdańsk –
401 *Cercopagis pengoi* and *Evadne anonyx*. Copepod dominated except for only a few short periods.
402 The maximum values of zooplankton abundance and biomass were observed in the summer
403 season, both in the Gdańsk Deep and the inner part of the Gulf of Gdańsk. Copepod dominated
404 in the composition of zooplankton for almost the entire duration of the research. Rotifers
405 occurred in larger numbers only in summer 2010 in Gdańsk Deep and in May and July 2010 in
406 the western part of the Gulf of Gdańsk, and meroplankton – in April 2011. This is a typical
407 pattern of seasonal changes in the zooplankton in this region. In the study season of 2006/2007,
408 Copepod also dominated in the zooplankton in the western part of the Gulf of Gdańsk (except for
409 June and July 2006, and May 2007) and Rotifera had a significant contribution during the spring
410 and summer season. Of the other components, only meroplankton had a considerable
411 contribution in the zooplankton (September 2006 – 10%; July – 24%) (Dzierzbicka-Głowacka,
412 Kalarus & Żmijewska, 2013).

413 **Changes in the abundance and biomass of zooplankton**

414 Taxa occurring in the samples occasionally or in small numbers (*Hyperia galba*, *Oithona similis*,
415 Ctenophora, freshwater Cyclopoida, Harpacticoida) were not included in the determination of
416 zooplankton abundance and biomass.

417 The average count of zooplankton in Gdańsk Deep (station P1) during the conducted studies was
418 10685 ind. per m⁻³ (SD 12027), whereas in 2011 – 14 607 ind. per. m⁻³ (SD 9565). The highest
419 mean values of abundance in the water column were recorded in the summer season of 2010

420 and 2011, i.e. 24238 ind. m⁻³ and 23659 ind. m⁻³, respectively. Minimum values were observed in
421 the winter-spring season (1283 ind. m⁻³ and 2807 ind. m⁻³) (Fig. 12) (Data S2).

422 The average count of zooplankton in the western part of the Gulf of Gdańsk (at station P2) in
423 2010 was 87 122 ind. m⁻³ (SD 104836), and in 2011 – 31 649 ind. m⁻³ (SD 20487). In 2010, the
424 maximum average count of zooplankton in the water column was recorded in July, whereas in
425 2011 – in September, i.e. 28 2166 ind. m⁻³ and 56 657 ind. m⁻³, respectively. The minimum
426 values were recorded in March 2010 (3617 ind. m⁻³) and April 2011 (7249 ind. m⁻³) (Fig. 13)
427 (Data S3).

428 Zooplankton at station P1 varied depending on the seasons, although not as much as in the
429 shallow regions of the Gulf of Gdańsk. In the two-year cycle of scientific studies, Copepod were
430 the main component of zooplankton, representing from 69% of the total zooplankton in spring
431 2011 to 96% in spring 2010 (except for summer 2010, ca. 18%) (Data S2).

432 In 2010 and 2011, Copepod occurred at station P2 throughout the study period and for most of
433 the months they were the main component of zooplankton, with the contribution ranging from
434 ca. 67% (in September) to 92% (in March) in 2010 and from 47% (in June) to 93% (in January)
435 in 2011, except for May (24%) and July (over 9%), when rotifers dominated in the zooplankton.
436 In August, the contribution of Copepod was similar to Cladocera and Rotifera and amounted to
437 ca. 40%. In 2011, the exceptions were April and July when pelagic fauna was dominated by
438 meroplankton – mainly veligers of bivalves (Data S3).

439 Copepod were the main component of the zooplankton biomass at station P1 for the whole
440 duration of the study, with the contribution ranging from 55.3% in summer 2010 to 99.2% in
441 winter 2010.

442 The situation was different at station P2. In March, April and June as well as in September,
443 October and November 2010, Copepod accounted for the main part of the zooplankton biomass,
444 i.e. from 67.6% in October to ca. 94.6% in March. In May, July and August, as a result of
445 seasonal zooplankton components occurring during these months (e.g. Cladocera), the proportion
446 of Copepod significantly decreased and ranged from 24.2 to 36.7%. In 2011, copepods
447 dominated at station P2, and their contribution in the total biomass ranged from 31.7% (in April)
448 to 96.7% (in January). In April, juvenile stages of the benthic fauna dominated in the
449 zooplankton biomass – 64.35%, while in the following months their contribution dropped to
450 7.03%, and then increased again in July – 34.95% (Lemieszek, 2013).

451 **Changes in the abundance and biomass of Copepod**

452 The coastal region of the Gulf of Gdańsk is wide open towards the Gdańsk Deep, which is part
453 of the Gdańsk Basin, the southernmost part of the Gotland Basin, i.e. the largest and the deepest
454 basin of the Baltic Sea.

455 The vertical profile of waters in the Gulf of Gdańsk can be divided into two layers. The surface
456 layer in the coastal area reaches the bottom. In the deeper part, it is separated from the lower
457 layer by intermediate waters up to 60-80m depth. The surface layer is subject to seasonal
458 changes in temperature, caused by meteorological factors, convection, wind mixing and the
459 impact of the Vistula River water, which causes warming in spring and summer and cooling in
460 autumn and winter. The impact of the Vistula River has a different range during the year, in
461 spring and summer it covers almost the entire gulf, while in November – it is limited to
462 estuaries. This is due to the force and direction of winds. There is a difference in the vertical
463 distribution between coastal and deep-sea regions. The coastal areas have higher temperatures in
464 summer compared to the surrounding waters, while in winter they are cooler. The annual report
465 shows that the salinity in the Gulf of Gdańsk is lower in winter than in summer. A key factor
466 affecting the salinity of surface waters are fresh waters from the Vistula River.

467 The environment of pelagic animals changes with the distance from the shore and with the sea
468 depth. Although the qualitative structure of zooplankton is almost identical with that of the
469 coastal waters, the quantitative structure changes quite significantly. There are more species
470 typical of colder and more saline waters, especially in the lower water layers. The abundance of
471 *A. longiremis* from the genus *Acartia* is higher compared to the coastal waters where *A. bifilosa*
472 and *A. tonsa* are the dominant species. Also the concentration of *Pseudocalanus* sp. and *T.*
473 *longicornis* is higher (Dzierzbicka-Głowacka et al., 2013; 2015).

474 Taxonomic composition of Copepod during the research conducted in the Gulf of Gdańsk at
475 station P1 (open sea), based on the quantitative contribution in the biomass, was different
476 compared to station P2 (the inner part of Gdańsk Gulf), which was attributed to a high
477 percentage of a crustacean that prefers waters with lower temperature and higher salinity –
478 *Pseudocalanus* sp.

479 In 2010 and 2011, *Pseudocalanus* sp. was the main component of Copepod at station P1 in the
480 winter-spring season (ca. 50% and 60% of the abundance and biomass, respectively), and in the
481 summer-autumn season its contribution dropped and was similar to that of *Temora longicornis*:

482 ca. 40% in summer and 35% in autumn. The percentage of the genus *Acartia* in these seasons
483 ranged from 10% to 30%.

484 Analysis of the variation in the Copepod taxonomic structure in the inner part of the Gulf of
485 Gdańsk at station P2 indicates that *Acartia* spp. dominated in the Copepod composition. Its
486 contribution in 2010 ranged from 26% (in March) to 89% (in September), and in 2011 – from
487 16% (in May) to 85% (in August), while in October and November – ca. 32%.

488 *Temora longicornis* was a sub-dominant species in terms of abundance and biomass of Copepod
489 in the Gulf of Gdańsk. Its maximum contribution in the total abundance at station P2 was ca.
490 45% (in November 2010) and 77% (in May 2011) and ca. 56% (in November 2010) and 80% (in
491 May 2011) in biomass.

492 **Abundance, comparison with the other data**

493 Taking into account the two periods – 2006/2007 (Kalarus, 2010; Dzierzbicka-Glowacka,
494 Kalarus & Żmijewska, 2013) and 2010/2011, the total count of Copepod in the Gdańsk Basin (at
495 station P2) was characterized by a significant increase (three- and twofold) in the maximum
496 abundance within the 10-0 m layer in May 2010 (161 150 ind. m⁻³) and within the 20-10 m layer
497 in July 2007 (127 000 ind. m⁻³), as well as in the average value in the water column, i.e. 67 790
498 ind. in May 2010 and 83 500 ind. in July 2007, compared to 2006 and 2011. In Lithuanian Baltic
499 Sea, at the coastal stations (B1-B4) and open sea stations (B5-B9) in 2014 (Data S6), the average
500 abundances of Copepod in surface layer (i.e. 36 320 and 21 327 ind. m⁻³) were similar to values
501 from 2011 and 2006 for the Gulf of Gdańsk and about two and four times lower than for 2011
502 and 2010, respectively. (Table 1).

503 In general, the maximum contribution (%) of *Acartia* spp., *Temora longicornis* and
504 *Pseudocalanus* sp. in the abundance of Copepod at station P2 in the western part of Gdańsk Gulf
505 was similar in the two periods – 2006/2007 and 2010/2011 (Table 2). The population dynamics
506 of the main Baltic calanoid copepod species in the Gdańsk Basin in the two study periods was
507 characterized by an increase in the maximum percentage contribution of *Acartia* spp. (up to
508 90%) and *Pseudocalanus* sp. (up to 29%) and a decline of *Temora longicornis* (to 45%) in the
509 abundance of Copepod in 2010 and a major growth (up to 77%) of *T. longicornis* in 2011, as
510 well as a decline of *Acartia* spp. and *Pseudocalanus* sp. in 2011 to the level from 2006/2007. In

511 the other cases, the percentage of individual taxa was at a similar level throughout the study
512 period.

513 The taxon *Acartia* spp. had the highest percentage contribution (ca. 82-90%) in all the studied
514 years, particularly in the summer (June-September). *Temora longicornis* accounted for ca. 45-
515 57% (i.e. almost half the *Acartia* abundance) of the total Copepod abundance in the studied
516 period (2006/2007 and 2010/2011; except for 2011 – 77%), i.e. late spring/summer (May/June)
517 or autumn (November) when soon after or before these periods *Acartia* spp. reached the first of
518 the second peak in the abundance, respectively. On the other hand, the highest contribution of
519 *Pseudocalanus* sp., the third most abundant Copepod species in the inner part of the Gulf of
520 Gdańsk, was observed in early spring (March/April – ca. 23-29%), except for 2006 (in February
521 – 25%). *Pseudocalanus* sp. is a typical representative of the winter zooplankton. Outside the
522 winter season, the taxon is present mostly in cooler, deepwater layers in the Gulf of Gdańsk
523 (Siudziński, 1977).

524 At station P1 (Gdańsk Deep) in 2010 and 2011, the maximum contribution (%) of *Acartia*
525 spp.(40-33%) was similar to that for *Temora longicornis* (33-45%) and two times lower than at
526 station P2. However, *Pseudocalanus* sp., had the highest percentage contribution (ca. 53-62%),
527 particularly in the spring (April).

528 The percentage contribution observed for this species in Gulf of Gdańsk (P1) was similar in
529 comparison to that observed in Lithuanian Baltic Sea on the open sea stations (B5-B9): for
530 *Acartia* spp. and *Temora longicornis* for the average values (in ()), in turn for *Pseudocalanus*
531 sp. for maximum value (in []) (Table 2).

532 **Conclusion**

533 Taxonomic composition of the zooplankton in the Gulf of Gdańsk appears to be stable. An
534 additional difficulty in comparing the data from different years results from different sampling
535 methods, especially the mesh size. It appears that contrary to the Gulf of Bothnia, the Gulf of
536 Finland and the Gulf of Riga, characterized by specific biocenoses (Ojaveer and Alken 1997),
537 the Gulf of Gdańsk is not isolated from the open-sea impact, which is evidenced by the high
538 similarity of zooplankton composition between the Gdańsk Deep and the coastal waters of the
539 Gulf of Gdańsk, and consequently the gulf represents the unique coastal ecosystem of the Baltic
540 Proper (Dzierzbicka-Głowacka et al., 2012).

541 Thorough knowledge of the species composition, the dominance of particular taxa, density and
542 biomass in combination with abiotic makes it easier to assess changes taking place in an
543 ecosystem. In combination with simulation models, such knowledge provides hypothetical
544 forecasts for the future, leading to anticipating the positive or negative effects of environmental
545 changes.

546

Figure 1

Location of the sampling stations (P1 and P2) in the southern Baltic Sea in 2010-2011.

Figure 2

Abundance of Copepoda at P1 station (the southern Baltic Sea – the Gdańsk Deep: 54°50'φN, 19°19'λE) in 2010-2011.

Figure 3

Taxonomic community structure of Copepod abundance at P1 station (the southern Baltic Sea - the Gdańsk Deep: 54°50'φN, 19°19'λE) in 2010-2011.

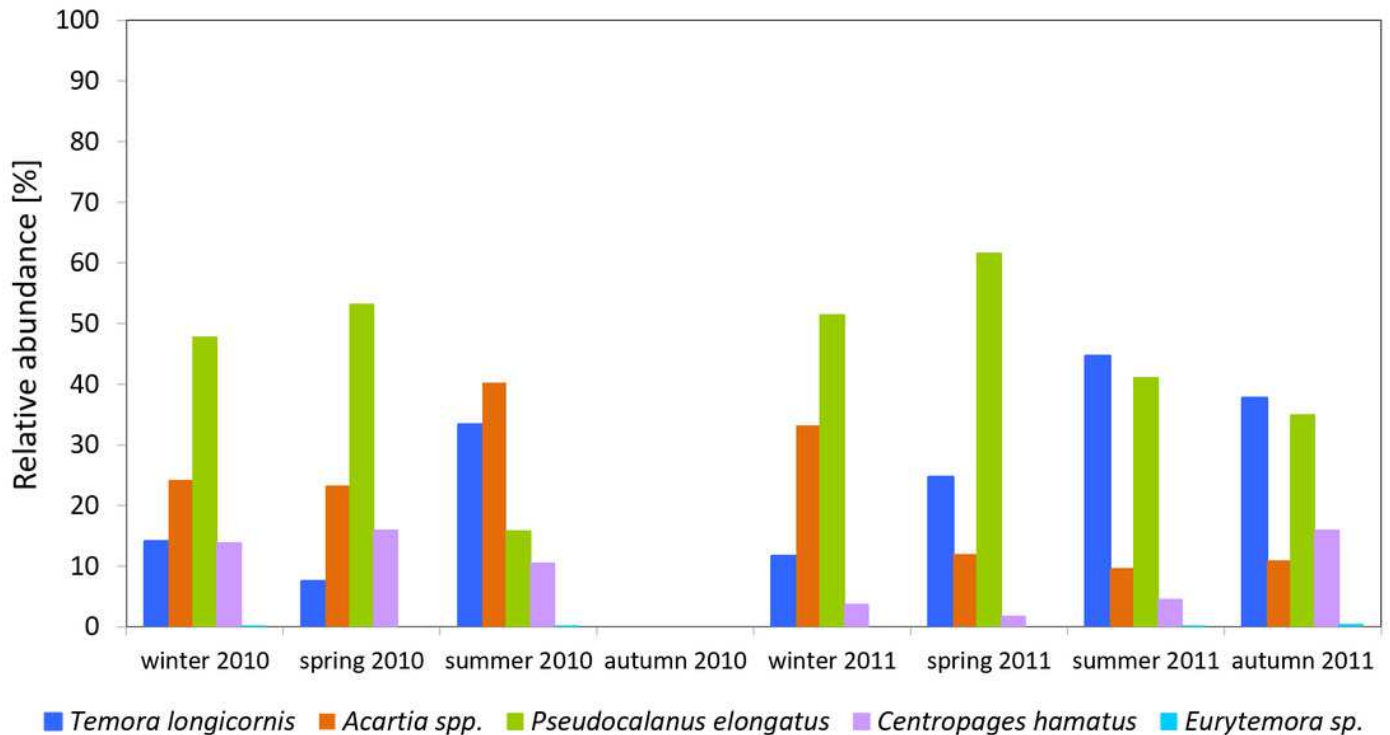

Figure 4

Abundance of Copepoda at P2 station (the southern Baltic Sea – the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2' λE) in 2010-2011.

Figure 5

Taxonomic community structure of Copepod abundance at P2 station (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2 'λE) in 2010.

Figure 6

Taxonomic community structure of Copepod abundance at P2 station (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2 'λE) in 2011.

Figure 7

Biomass of Copepod at P1 station (the southern Baltic Sea - the Gdańsk Deep: 54°50'φN, 19°19'λE) in 2010-2011.

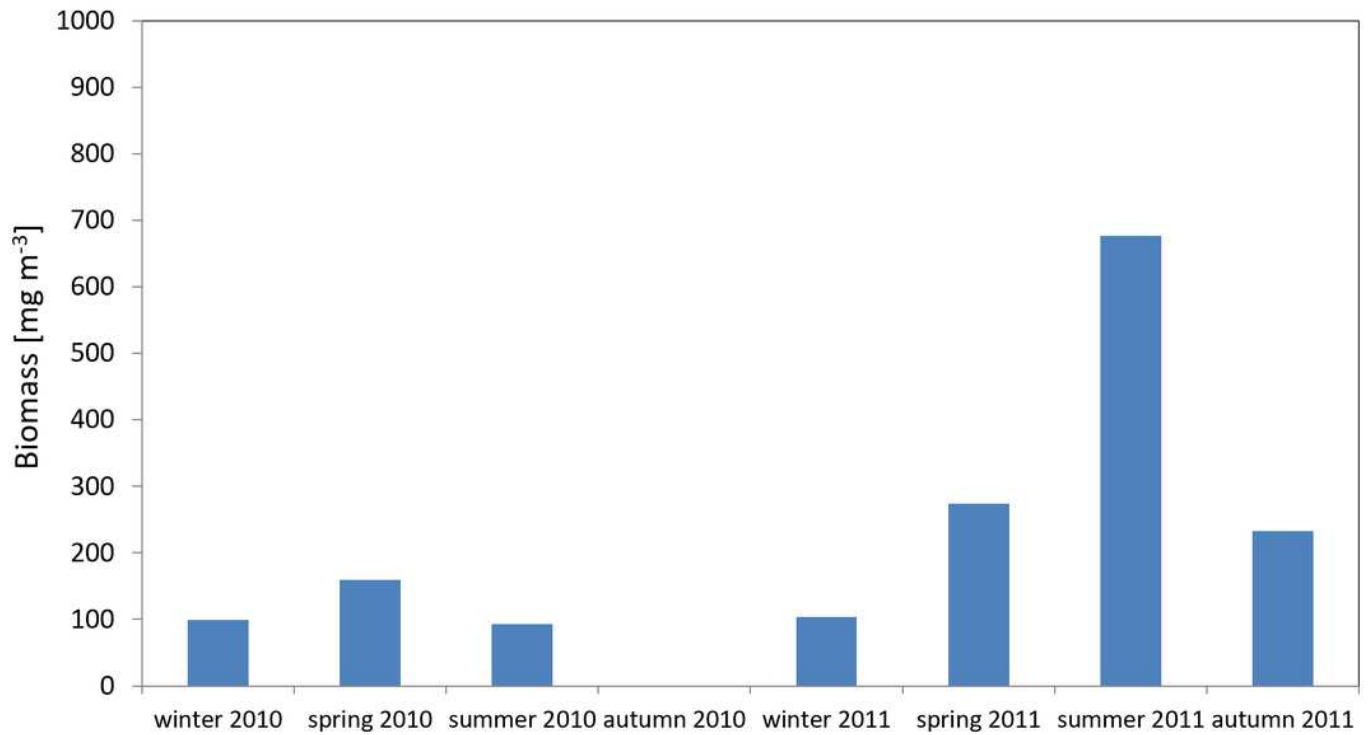

Figure 8

Taxonomic community structure of Copepod biomass at P1 station (the southern Baltic Sea - the Gdańsk Deep: 54°50'φN, 19°19'λE) in 2010-2011.

Figure 9

Biomass of Copepod at P2 station (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2' λE) in 2010-2011

Figure 10

Taxonomic community structure of Copepod biomass at station P2 (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2 'λE) in 2010.

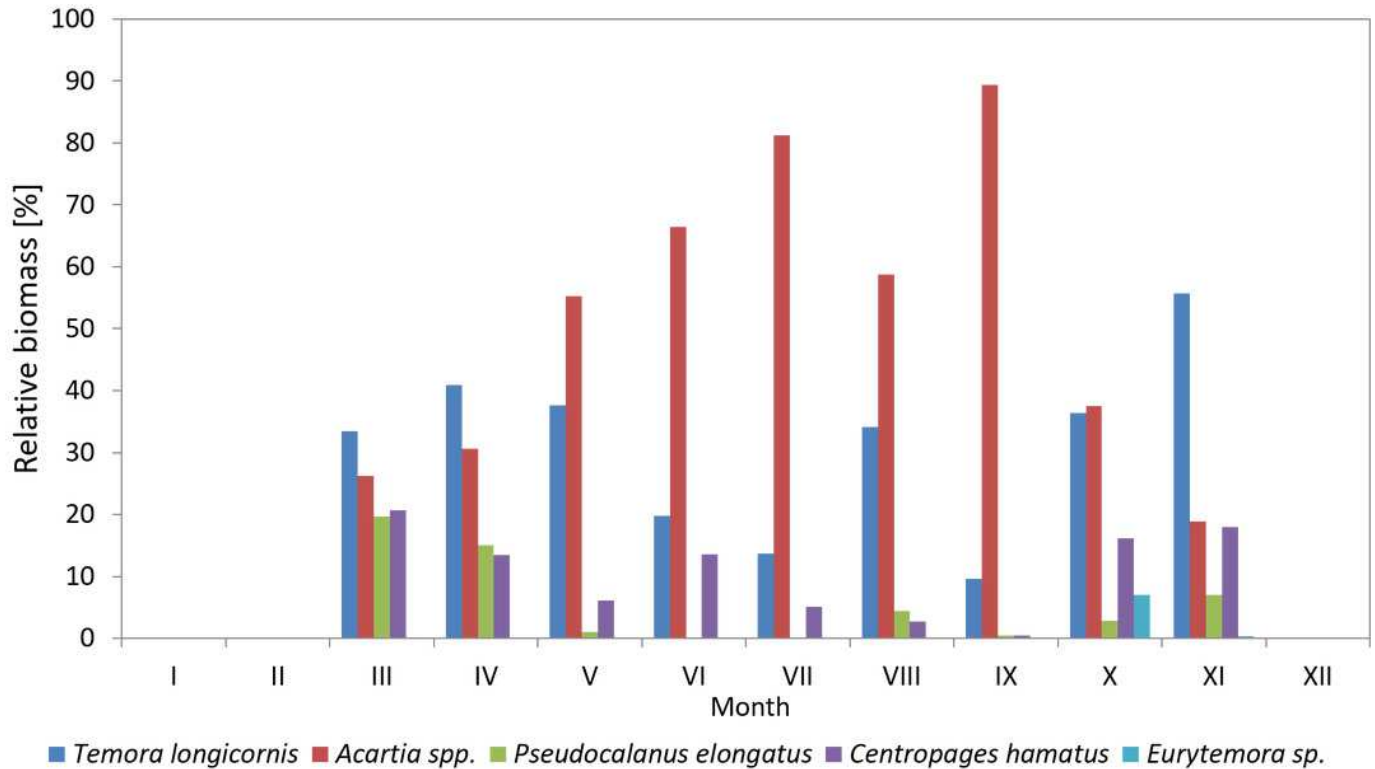

Figure 11

Taxonomic community structure of Copepod biomass at P2 station P2 (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2 'λE) in 2011.

Figure 12

Zooplankton abundance at P1 station (the southern Baltic Sea - the western, inner part of the Gulf of Gdańsk: 54°32' φN, 18°48.2' λE) in 2010-2011

Figure 13

Zooplankton abundance at P2 station (the southern Baltic Sea – the Gdańsk Deep: 54°50'φN, 19°19'λE) in 2010-2011

Table 1 (on next page)

Abundance (ind. m⁻³) – max (left column) and mean (right column) of *Acartia* spp., *Temora longicornis*, *Pseudocalanus* sp. at station P2 in the Gulf of Gdańsk and at stations B1-B4 and B5-B9 in Lithuanian Baltic Sea.

Data from the Gulf of Gdańsk for 2006 and 2007 (Kalarus, 2010), 2010 and 2011 (Lemieszek, 2013) – unpublished data. Data from Lithuanian Baltic Sea coastal stations (B1-B4)* and open sea stations (B5-B9)** for 2014 – unpublished data.

1

year	max ind. m ⁻³ (month and layer)	average ind. m ⁻³ (month)
2006	57 500 (July in 40-30 m)	25 600 (June)
2007	127 000 (July in 20-10 m)	83 500 (July)
2010	161 150 (May in 10-0 m)	67 790 (May)
2011	70 300 (Sept. in 10-0 m)	39 560 (Sept.)
2014*	40 317 (July in 25-0 m)	36 320 (July)
2014**	43 912 (July in 25-0 m)	21 327 (July)

2

Table 2(on next page)

Maximum contribution (in %) of *Acartia* spp., *Temora longicornis* and *Pseudocalanus* sp. to the total abundance of Copepoda at stations P1 and P2 in the Gulf of Gdańsk and at stations B1-B4 and B5-B9 in Lithuanian Baltic Sea.

Data from the Gulf of Gdańsk for 2006 and 2007 (Kalarus, 2010), 2010 and 2011 (Lemieszek, 2013) - unpublished data. Data from Lithuanian Baltic Sea coastal stations (B1-B4)* and open sea stations (B5-B9)** for 2014 - unpublished data. [] - Max % in separate station from stations B1-B4 and B5-B9; () - Averaged per stations B1-B4 and B5-B9.
