#### 20 Abstract

Bat populations are known to be affected by anthropogenic activities because bats are an 21 extremely diverse group occupying almost all available niches in terrestrial environment. Hence, 22 23 bats are considered bioindicators to monitor changes in the environment, but their value as such also depends on the ease to monitor and detect demographic trends in their populations. The 24 long-term interest of researchers in the acoustic of bats results from the fact that it is a non-25 invasive, time-efficient method to monitor spatiotemporal patterns of bat diversity and 26 activity. The analysis of sounds emitted by organisms has been considered useful to gain insight 27 into species-specific biotic and abiotic interactions, which can further be applied to conservation. 28 Besides manual identifications of bat calls, some automated species identification programs 29 using regional call classifiers have been introduced into the market as an effective tool in the 30 31 monitoring of bat populations. Most of these programs have not been validated using field data. This study evaluates the reliability of two automated software, SonoChiro, and Kaleidoscope 32 Pro, in comparison to manual identifications of field data collected from the Neotropical region. 33 There was low agreement between the two automated methods at the species level, fair 34 agreement at the genus level and moderate agreement at the family level. There was also a 35 significant difference between the proportions of correctly identified calls of the two-automated 36 software at the species level identifications. Major challenges for using automated identification 37 software include the need for comprehensive call libraries of the regions under scope; significant 38 opportunities, on the other hand, include the widespread possibility to monitor spatiotemporal 39 patterns of bat activity. Overall, there are serious gaps that preclude a widespread application of 40 automated programs ecological and conservation studies of bats, but it has the potential to serve 41 42 as a useful tool.

#### 44 Introduction

Most bat species produce ultrasound for orientation, navigation and hunting prey (Adams 45 and Pedersen 2013). Bats emit a signal (pulse) of a certain frequency and then perceive the 46 reflected signal (echo) which returns after hitting a target or surrounding objects in the 47 48 environment (Schnitzler and Kalko 2001; Fenton 2003; Adams and Pedersen 2013). These ultrasounds produced by bats are known as echolocation calls and have co-evolved over time 49 50 depending on various ecological and physical factors (Murray et al. 2001; Obrist et al. 2007). 51 When hunting for prey, bat echolocation calls are characterized by three phases: search phase, 52 approximation phase and terminal buzz phase (Murray et al. 2001). Echolocating bats use tonal 53 signals with structured changes in frequency over time ranging between 8 and 200kHz (Fenton 2003; Adams and Pedersen 2013). Bats also produce social calls when mating, foraging, and 54 during distress, aggression and mother-offspring interactions (Wilkinson and Boughman 1998; 55 Fenton 2003; Budenz et al. 2009; Furmankiewicz et al. 2011). Echolocation and social calls are 56 species- specific and, in some cases, even colony-specific (Fenton 2003). 57 Biologists characterize bat calls using parameters of the pulse such as frequency 58 modulation (FM), harmonic level, duration (D or t), inter-pulse interval (IPI), frequency of 59

60 maximum energy (FME), maximum frequency ( $F_{max}$ ), minimum frequency ( $F_{min}$ ) and bandwidth

61 (BW=  $F_{max}$ - $F_{min}$ ) (**Figure 1**). This is used it to identify the calls to species level.

Bats are nocturnal mammals, difficult to catch and sensitive to anthropogenic intrusion which make them difficult to account for only using traditional capturing methods with mist nets or harp traps (MacSwiney et al. 2009; Russo and Voigt 2016). Acoustic monitoring has emerged as a non-invasive, time-efficient method which can be used to study spatiotemporal patterns of

bat diversity and activity (Russo and Voigt 2016; Silva et al. 2017; Stathopoulos et al. 2017) and
is not limited by inaccessible environments or adverse weather conditions (Skalak et al. 2012;
Marques et al. 2016). Acoustic monitoring has helped researchers gain knowledge about bat
behavior, habitat preferences, foraging strategies, distribution, abundance, population trends and
about species that are difficult to capture (Miller and Degn 1981; Fenton et al. 1987; Vaughan et
al. 1997; Verboom et al. 1999; Marques et al. 2016; Stathopoulos et al. 2017).

72 Manual species identification of acoustic calls by experts using identification keys specific to an area is considered a reliable method, but the problem arises with large data sets 73 where identification becomes time-consuming. The concept of automated species identification 74 has been argued to have consistency, predictability, high levels of accuracy and measures of 75 uncertainty (Jennings et al. 2008) which can be standardized over studies. The automated 76 methods used in the past to quantify call parameters to classify animal calls include discriminant 77 function analysis (Parsons and Jones 2000; Pfalzer and Kusch 2003; Broders et al. 2004; 78 79 Preatoni et al. 2005; MacSwiney et al. 2009; Adams et al. 2010; Clement et al. 2014), cluster 80 analysis (Preatoni et al. 2005), classification trees (Sattler et al. 2007), artificial neural networks 81 (Preatoni et al. 2005; Jennings et al. 2008; Adams et al. 2010; Parsons and Jones 2000) and deep machine learning tools (Walters et al. 2012; Hackett et al. 2016). Jennings et al. (2008) compared 82 83 identifications done manually with those of artificial neural networks (ANNs) and found that ANNs performed better than 75% of humans in the study. Walters et al. (2012) developed a 84 continental-scale acoustic identification tool for European bats, which was confirmed to provide 85 86 robust classification.

87 The Neotropics show a very high diversity of bats with numerous gaps in knowledge 88 about their ecology, behavior, acoustic classification and conservation status (Zortéa and Alho

2008; Adams and Pedersen 2013). Bats of this region, as well as other areas, are under threat due 89 to changes caused by anthropogenic activities such as alteration of land-use, invasive species, air, 90 91 water and noise pollution (Aguiar et al. 2016; Mendes and De Marco 2017). Therefore, the need for efficient and accurate species identification methods for more extensive areas has rapidly 92 escalated and resulted in the availability of much automated software in the market. SonoChiro 93 94 and Kaleidoscope are two such programs that have been used in previous studies for automated species identification with region-specific call classifiers and careful speculation (Slough et al. 95 2014; Michaelsen 2016; Toffoli 2016). Even though the producers of the software insist that the 96 accuracy rates are high, researchers are aware of the inaccuracies and use manual identifications 97 for certain species most of them have never actually been tested on field data (Russo and Voigt 98 2016). Lemen et al. (2015) used unidentified field data to compare the performance of 4 99 automated programs and found an average pair-wise agreement of 40%. More recently a study in 100 Sweden showed poor performance of classifiers used by Kaleidoscope Pro and SonoChiro 101 102 because the identifications were not reliable (Rydell et al. 2017). 103 The performance of such software has already been evaluated for temperate species, but the performance of the available Neotropical software and their respective classifiers has not been 104 validated previously. The challenge of using automated identification for Neotropical species is 105

that there is a lot of evidence showing inter and intraspecific variability of bat calls due to high
species richness (Jones et al. 1992; Jones 1997; Barclay et al. 1999; Murray et al. 2001; Pfalzer
and Kusch 2003; Broders et al. 2004; Russ et al. 2004; Jung et al. 2007; López-Baucells et al.
2017).

The aim of this study is to evaluate the reliability of two automated programs (SonoChiro
and Kaleidoscope Pro) that are widely used for automated identifications, for Neotropical bat

species. The agreement between the two automated and manual identifications for the same dataset was predicted to be low at species and genus level identification but not at the family level. Using the manual identifications as absolute true species, the second hypothesis was that there would be a difference in the proportion of correctly identified between the two-automated software. SonoChiro was predicted to perform better than Kaleidoscope because SonoChiro can give group (family and genera) and species level identifications separately while Kaleidoscope uses only species classifiers (Rydell et al. 2017).

#### 119 Materials and methods

#### 120 Field Collection

Our study species included eight out of nine families of Chiroptera found in Brazil, 121 122 namely Emballonuridae, Furipteridae, Molossidae, Mormoopidae, Natalidae, Noctilionidae, 123 Thyropteridae and Vespertilionidae. In Brazil, these families cover a total of 93 species, of at least 178 occurring in Brazil (Nogueira et al. 2014). The recordings were collected at two sites at 124 10 different sampling points at the National Park of Brasília in the city of Brasilia, Federal 125 126 District, which is situated in the core area of the Brazilian Cerrado. The Cerrado is composed of woodlands, savannas, grasslands and dry forests and forms the second largest biome of Brazil 127 (Klink & Machado 2005) and 40% of its mammals are bats (Aguiar et al. 2016). The recording 128 129 was made over two periods, August and September 2016, which correspond to the middle and 130 the end of the dry season respectively. The SM2 Bat detector (Wildlife Acoustics, U.S.A; www.wildlifeacoustics.com) was used to record bat calls at the sites, without using any filter for 131 the ambient noise. The data used for this paper was secondary data collected under the license 132 number #27719-13 issued by SISBIO/ICMBIO, which is the institution that grants permits to 133 134 work in protected areas.

Each recording had lasted four minutes. To carry out call analyses, the recordings had to be cut into 15-second intervals using Kaleidoscope, as the automatic identification software can only process files with a maximum duration of 15-seconds. A total of 49,783 WAVE files were extracted and again processed using the same software to filter out empty files. Finally, the remaining number of recordings added up to 3,465 15-second duration files.

#### 140 Automated identification of recordings

For the automated identification, the 3,465 15-second duration files were analyzed using 141 142 SonoChiro v.3.0 (Biotope, France www.biotope.fr) and Kaleidoscope Pro 3.14B (Wildlife 143 Acoustics, U.S.A; www.wildlifeacoustics.com). The settings used were: for SonoChiro - type of 144 recorder (SM2 Bat), region (Amazonian basin), time expansion (x1), maximum call duration 145 (0.5), sensitivity (7), for Kaleidoscope Pro – filter noise files (keep noise files), signal of interest (8-120kHz, 2-500ms, minimum two calls), classifiers (Neotropical bats), (0 Neutral sensitivity). 146 147 The sensitivity scale of SonoChiro ranges from 10 to 0 and that of Kaleidoscope is +1 to -1. 148 They are calculated differently but essentially range between giving results for low quality pulses (more sensitive) and only high-quality pulses (more accurate). The output generated by the two 149 automated programs is expected to show group and species level identifications. The 150 identifications that may not be attempted result in "parasi" (SonoChiro), "no ID" or "Noise" 151 (Kaleidoscope Pro). 152

#### 153 Manual identification of recordings

The identifications were made manually on 44% of the recordings used for automated identifications (1506 WAVE files) using Avisoft SASLab Pro (Specht 2004). The spectrogram for each recording was created using the following parameters: FFT length (1024), frame size (100%), Overlap (87.5%) and Hamming window. The parameters determine the frequency and

time resolution of the pulse or sequence in the spectrogram. Frequencies below 10kHz were 158 filtered out using noise filter for better identification. The recordings attempted to be manually 159 identified required at least three clear pulses and any overlapping pulses were discarded to avoid 160 any bias. The parameters that were observed and tabulated to identify the calls up to species level 161 were: i) average call duration of at least three pulses; ii) number of harmonics and maximum 162 energy harmonic; iii) number of call types; iv) pulse structure (FM, CF or qCF); v) frequency of 163 maximum intensity (FME); vi) maximum frequency (Fmax); vii) minimum frequency (Fmin); 164 viii) bandwidth (BW); and ix) inter-pulse interval (IPI) (Figure 1). Some additional parameters 165 were measured when required, such as initial frequency (F<sub>intial</sub>), end frequency (F<sub>end</sub>) and 166 individual parameters of different call types. The identification was done using an Illustrated 167 identification key to the calls of Brazilian bats (Arias-Aguilar et al. submitted). 168

#### 169 Statistical analysis

170 The data compiled for statistical analysis included family, genus and species level 171 identifications for the automated programs (SonoChiro and Kaleidoscope Pro) and manual identifications. The agreement between the three sets of identifications for each of the levels 172 173 (family, genus and species) was tested using the inter-rater reliability Fleiss's kappa statistic (Dunn 1992). Further, the manual identifications were assumed as true identifications and the 174 number of correctly identified recordings were recorded for each of the automated software. 175 Overall difference in proportion of correctly identified files at each level (species, genus and 176 family) between the two automated programs was computed using Chi-squared tests. True 177 positives, false positives, true negatives and false negatives for each species were calculated for 178 179 SonoChiro and Kaleidoscope Pro. True positives of each software were all the identifications of a species matched with manual identifications. False positives were those where the presence of 180

181	species was identified incorrectly by the software while false negatives were those where the
182	species was present but not perceived by the software. True negatives were calculated by
183	accounting for all the recordings where other species were identified.
184	Results
185	A total of 643 and 274 WAVE files were not identified by the automated programs and
186	manually by an expert, respectively. Therefore, these were removed, and the remaining 602
187	WAVE files were used for the further analyses.
188	Agreement between two automated and manual identifications
189	Following Dunn (1992) agreement level described as Poor if $\kappa$ <0.00, Slight if $0.00 \le \kappa \le$
190	0.20, Fair if $0.21 \le \kappa \le 0.40$ , Moderate if $0.41 \le \kappa \le 0.60$ , Substantial if $0.61 \le \kappa \le 0.80$ and
191	Almost perfect $\kappa > 0.80$ , the Fleiss's kappa statistic value showed that there was low agreement
192	between the three sets of identifications at the species level ( $\kappa$ =0.145), fair agreement at the
193	genus level ( $\kappa$ =0.326) and moderate agreement at the family level ( $\kappa$ =0.456). The total number
194	of recordings that were agreed on at the species, genus and family level was 23, 89 and 285
195	WAVE files respectively (Figure 2).
196	Comparison of the proportion of correctly identified files
197	There was a significant difference between the proportion of correctly identified recordings by
198	two automated programs at the species level ( $X^2 = 280.54$ , df =1, p <0.05) and family level ( $X^2 = 280.54$ , df =1, p <0.05)
199	20.917, df =1, p <0.05) ( <b>Figure 3</b> ). The percentage of correctly identified species by SonoChiro
200	and Kaleidoscope Pro was 5%. At the family level, 77% of the recordings were correctly

- 201 identified by SonoChiro and 65% was correctly identified by Kaleidoscope Pro. There was no
- significant difference between the proportions of correctly identified files by the two automated

203	programs at the genus level ( $X2 = 1.608$ , df =1, p >0.05). The percentage of correctly identified
204	genera was 48% for SonoChiro and 52% for Kaleidoscope Pro.

#### 205 Correctly and misidentified species by automated software

In Table 1 is shown the number of true positives, false positives, true negative and false 206 negatives calculated for each species manually identified from the 602 WAVE files: Eptesicus 207 208 brasiliensis, Eptesicus furinalis, Lasiurus blossevillii, Lasiurus ega, Molossus currentius, Molossus Molossus, Molossops temminckii, Myotis lavali, Myotis nigricans, Myotis riparius, 209 210 Peropteryx leucoptera/palidoptera, Peropteryx macrotis, Promops nasutus and Pteronotus 211 parnellii. The genera Cynomops, Eumops, Nyctinomops and Tadarida could not be manually 212 identified to the species level. The species of genera *Myotis* and *Peropteryx* had no true 213 positives for Kaleidoscope Pro but SonoChiro identified two out of five Myotis riparius and the only Peropteryx macrotis call correctly. Eptesicus brasiliensis, Molossus currentium, Promops 214 nasutus and Pteronotus parnellii were misidentified by both programs. Lasiurus ega calls were 215 identified correctly by Kaleidoscope Pro but not by SonoChiro in the two instances it was 216 present. Most Eptesicus furinalis calls were identified correctly by SonoChiro (9 out of 10) and 217 Kaleidoscope (7 out of 10) but they had 148 and 18 false positives respectively. Almost 88% of 218 Lasiurus blossevillii calls were identified correctly by Kaleidoscope but none by SonoChiro. 219 Species of Molossidae, Molossus and Molossops temminckii, were identified correctly 80.5% and 220 84% of the time respectively. On the other hand, SonoChiro misidentified 80% Molossus and all 221 Molossops temminckii calls. 222

#### 223 Discussion

The low agreement between the three different methods, two automated and one manual, for species identification raises a concern about the reliability of automated species identification

### NOT PEER-REVIEWED

## Peer Preprints

for bat monitoring and studies in the neotropics. Bats, unlike birds and other echolocating
animals, alter certain parameters of their calls depending on their interaction with the
environment or other species (Jones 1997; Kalko and Handley 2001; Chaverri et al. 2010). This
would make it difficult to distinguish between individuals in species-rich areas, such as the
Neotropical region, where certain bats species might occupy similar niches and hence would
have overlaps in call structures.

#### 232 Classification methods

233 Lemen et al. (2015) suggested that the low levels of agreement between software could 234 be because of recordings collected with different recording devices but in our study the call 235 database was the same and recorded using the same bat detector. This discrepancy could be 236 attributed to the difference in sensitivity scale, classification method and the classifiers used by each of the methods. The sensitivity setting in the software allows researchers to manipulate the 237 detectability of a call in the recording i.e. high sensitivity setting would detect even low-quality 238 pulses and low sensitivity setting would detect only high quality, clear pulses. Even though both 239 the software were set at similar sensitivity, SonoChiro can detect and classify more calls 240 compared to Kaleidoscope Pro. In the presence of more than one species in one recording, 241 SonoChiro has the ability to identify up to three species while Kaleidoscope identifies only what 242 it perceives as the dominant call in the recording. Also, considering classification methods, 243 SonoChiro detects any calls present on the recording and then classifies them using Random 244 Forest classification method, which in this case uses active learning/ negative labelling (Bas et al. 245 2013). This method is supposed to have a powerful confidence index and can spot obvious errors 246 247 in calls from diverse sources (Beard 2007; Cutler et al. 2007). On the other hand, the classification method of Kaleidoscope Pro uses error rates calculated from the confusion 248

### NOT PEER-REVIEWED

## Peer Preprints

matrices of specific regional classifiers to determine the most likely distribution of the different 249 species. The error rates for confusion matrices from different geographic regions and habitat 250 types might be different leading to misidentifications (Agranat 2012). To reduce the 251 misidentification rates, SonoChiro computes confidence levels for group and species level 252 identification while Kaleidoscope can give possible alternative identifications for the data; both 253 254 retrieve unknown classifications. Previously used automated identification methods were not able to provide confidence levels, alternative and unknown classifications; the lack of these 255 variables might result in higher levels of misidentifications and has been criticized (Adams et al. 256 2010). 257

Reliable manual identifications are dependent on the level of expertise of the observer and the identification key used for species identification. There is a level of aptitude that can be acquired and applied, which allows the detection of certain patterns or variations when recordings are manually identified but this also adds an unquantifiable uncertainty in the identifications (Jennings et al. 2008; Rydell et al. 2017). An advantage of using automated identifications is that the results can be combined, and a quantifiable uncertainty can be accounted for by using statistical methods (Russo and Voigt 2016)

#### 265 Intraspecific variation and interspecific overlap

Although, SonoChiro showed discrepancies when compared to manual identification, there was a gradual improvement from species to genus to family level identifications. Kaleidoscope could correctly identify more species than SonoChiro, but it only gives species level identification with no confidence indices. Therefore, SonoChiro might be at a better advantage as it is able to identify certain individuals at least up to the genus level. This information can be useful to survey and monitor specific focal genera (Rydell et al. 2017). At the

species level, there were some species correctly identified by one or the other software but only 272 Eptesicus furinalis and some Molossus calls were correctly identified by both. Eptesicus furinalis 273 274 was often misidentified as *Lasiurus blossevilliii* probably because the two species have similar call structures and frequency ranges. The main difference noted while manually identifying these 275 species is the transition of the downward frequency modulation  $(FM_d)$  to quasi constant 276 277 frequency (qCF), that is highly marked by a sharp edge in *E. furinalis* as compared to a curved one for L. blossevillii (Arias-Aguilar et al. submitted). The species of the genus Myotis were 278 mostly misidentified by both software programs. Previous studies using automated 279 identifications also refer problems when distinguishing *Myotis* species; in fact, this genus, while 280 highly specious and widespread worldwide, tends to show very similar call designs level and 281 suggest that *Myotis* species tend to have very similar call designs and frequency ranges, probably 282 due to phylogenetic constraints (Parsons and Jones 2000; Rydell et al. 2017) and, eventually due 283 to ecological convergence. *Myotis lavali* was only recently described as a separate species from 284 285 *Myotis nigricans* complex and a possible sympatry of these species has been suggested (Moratelli and Wilson 2013). SonoChiro was able to identify the genera *Peropteryx* and 286 287 *Pteronotus* correctly almost 100% of the time but at species level it failed to do so. Species of 288 these genera, as well, share call design and frequency ranges; therefore, we suggest that the call parameters considered for species level identification might be too similar for the software to 289 290 classify. On the contrary, Kaleidoscope misidentified all the calls of the genera *Peropteryx* as *Centronycteris* and *Pteronotus* as *Noctilio*, possibly because of interspecific overlaps amongst 291 292 these species. The genera *Peropteryx* and *Centronycteris* are from the family Emballonuridae and have similar call structure with qCF component (Jung et al. 2007). Similarly, genera 293 Pteronotus and Noctilio have similar call structure with CF -FM component but are from 294

different families (Suga 1990).

Misidentifications can be explained by the intraspecific variation in bat calls. Indeed, 296 species show acoustic geographic variation (Barclay 1999; Murray et al. 2001; López-Baucells et 297 al. 2017). Arias-Aguilar et al. (submitted) presents a revision of geographical call variation in 298 Brazilian bats; according to these authors at least ten species of bats present regional variation 299 above 10kHz difference in the FME parameter. At the intraspecific level, bats may also show 300 301 variation according to habitat type (Surlykke and Moss 2000; Schnitzler and Kalko 2001; Broders et al. 2004; Guillén-Servent and Ibáñez 2007; Jung et al. 2007), foraging mode and diet 302 (Fenton 1986; Jones 1997; Kalko and Handley 2001; Chaverri et al. 2017). All measurements for 303 304 cryptic species Pteronotus cf. rubiginosus varied between individuals recorded in Central Amazon and French Guiana (López-Baucells et al. 2017). It has been shown that bats emit 305 higher frequency, short duration calls when they are in areas of higher clutter or foraging at 306 habitat edges as compared to their conspecific foraging in open spaces (Barclay et al. 1999; 307 308 Surlykke and Moss 2000; Schnitzler and Kalko 2001; Broders et al. 2004; Jung et al. 2007; 309 López-Baucells et al. 2017). Sex and age also have been shown to cause variation among 310 individuals (Jones et al. 1992; Murray et al. 2001). Peak frequency of bat calls of species from the Vespertilionidae and Emballonuridae have shown to decrease with increase in body size 311 312 (Barclay et al. 1999; Jung et al. 2007). Individuals also tend to alter their calls to differentiate 313 their reflecting calls from their conspecifics (Obrist 1995; Ulanovsky et al. 2004; Adams and Pedersen 2013). Chaverri et al. (2017) showed also that certain species of the Molossidae modify 314 315 their calls by decreasing frequency and increasing call duration in order to cancel out atmospheric attenuation, which is caused due to complex interaction between temperature and 316 humidity. 317

### NOT PEER-REVIEWED

## Peer Preprints

Misidentifications may also be explained by interspecific overlap in call parameters. Interspecific overlap tends to occur amongst species that occupy similar ecological niches (Schnitzler and Kalko 2001) because they adopt similar call designs to navigate and forage in similar environments.

#### 322 Classifiers used by automated software

Considering the intra and interspecific variation as one of the major source of 323 misidentification, it would be appropriate to suggest that the classifiers used by the automated 324 325 programs might not be reliable. They might not include calls from different region or habitat 326 types which account for the variability discussed above. Also, they could be missing certain 327 species that are not found in the region from where the reference calls were collected. For 328 example, Molossops temminckii, Pteronotus parnellii, Eptesicus brasiliensis and Molossus *currentium*, which were largely misclassified by SonoChiro, are not included in the Neotropical 329 330 classifier used by the software. Therefore, we argue that the classifiers used for automated 331 identification should be specific to a region. Another factor which could jeopardise the accuracy of a classifier, i.e. the probability of correctly classifying a randomly selected recording (Fielding 332 and Bell 1997), are the calls used as reference. Reference calls used for classifiers are of 333 extremely good quality and should be that way, i.e. calls recorded from captured individuals and 334 close to important roost sites (Lemen et al. 2015). However, field recordings often are of much 335 lower quality. Classifiers should thus include calls recorded in a myriad of situations as to 336 include the maximum variability acoustically expressed by a species. Currently, it is clear that 337 the SonoChiro and Kaleidoscope Pro classifiers still do not account for the intraspecific variation 338 339 required to make accurate species level identifications. The classification methods also need to include additional parameters for distinguishing acoustically similar species. Because classifiers 340

341	are regionally or quantitatively limited (Adams et al. 2010), they should not be used as the only
342	source of identification in monitoring and surveying of bats until this barrier is overcome.

#### 343 The choice of relevant call parameters for species identification

Call structure and harmonics are usually enough for information about the family and 344 often also genus. However, species identification implies measurements of additional 345 346 parameters, ideally measured in several calls or pulses (Adams et al. 2010; Adams and Pedersen 2013). For example, the differentiation between *Peropteryx* species is based on FME. However, 347 348 because FME intervals slightly overlap between species, FME measurements may often not be 349 enough for species discrimination. Walters et al. (2012) established a continental scale tool for 350 acoustic identification of European bats using 12 different parameters to characterize frequency 351 and time course of the call and this tool was tested to give robust classifications. Still, it was unable to give reliable identifications in several occasions. This means that more parameters may 352 be necessary for discriminating species with very similar calls. 353

#### 354 Application Framework

Considering the limitations of automated acoustic software, we provide an application 355 356 framework, which can potentially be used to gain more information about species of bats in ecology and conservation field. Figure 4 represents a schematic diagram of a possible 357 application framework for automated bioacoustics software. The challenges that exist in applying 358 359 acoustics to monitor biodiversity are the need for robust identifications to species level and the ability of acoustic surveys to provide reliable information about population trends (Walters et al. 360 2012; Adams and Pedersen 2013; Frick 2013). Ecological and conservational studies are 361 complementary to an extent because information produced by the first would benefit the latter 362 field and vice-versa. 363

Currently, automated identification programs are capable of providing preliminary 364 information to focus research efforts in a certain area. Further improvements can be achieved by 365 accounting for the intraspecific variability and interspecific overlap of bat calls (Russo and Voigt 366 2016). Using acoustic filters to extract more specific call parameters could also prove beneficial 367 to differentiate at the species level (Clement et al. 2014). Other important aspects to consider 368 before automated species identification is applied to the data collected, in particular the 369 standardization of sampling methods, the implementation of statistically powerful sampling 370 designs, and systematic and long-term sampling (Sampaio et al. 2003; Skalak et al. 2012; Adams 371 and Pedersen 2013). 372

Bat detectors can be distributed over large areas over several days and can record several 373 hours of data from different areas simultaneously. Automated species identification can be 374 optimized and used as a very powerful tool to efficiently study and monitor spatiotemporal 375 patterns of bats globally if all the above conditions are met. Good quality ultrasound recordings 376 377 can be uploaded into these programs and some useful information can be extracted. While both software retrieves species identification, SonoChiro includes confidence indices with group and 378 379 species identification, number of bat passes, records of feeding buzzes and the presence of social calls. An important aspect to consider is that the identification software should either be tested 380 381 for the region or confirmed manually before being applied to the objectives described in the subsequent sections. 382

383 Species richness and composition

Studying the assemblage of bats in an area requires information about individual species to calculate species richness and to determine species composition (Briones-Salas et al. 2013; Mendes et al. 2014). Both the automated programs give species level identification. To calculate

species richness, the number of species identified by the software might be sufficient; even if
some species are misidentified, if there is a certain level of certainty that what is interpreted as
two different species are indeed so, richness estimates may be reasonably accurate. For species
composition, on the other hand, the identifications must be accurate. In this case, it would be
better to use the highest level of sensitivity in the program which will retrieve results only for
only high-quality pulses. Further confirmation, using supervised identifications of a certain
percentage of randomly chosen calls, might be required before using this information.

#### 394 *Density, abundance and activity*

One of the main challenges to overcome is monitoring bat populations with acoustics is gathering information on densities or abundances, as two bat-passes from the same species may result from two recorded individuals or from one individual flying twice over the bat detector. Until we develop means to individually identify each bat, only occurrence models and activity indexes may be attained.

Bat activity recorded from large number of sites may be used for determining habitat preferences by bats; similarly, bat activity recorded through time at the same site may reveal if there is a decrease or increase in the use of that site by bats, and indicate, a decrease or increase in the quality of the environment.

The number of feeding buzzes has been used as a proxy of foraging activity (Miller 2001; MacSwiney et al. 2009), may be especially relevant for determining foraging habitats and thus help in spatially prioritization for bat conservation. The presence of social calls has been considered an indication of a nearby roost (Chaverri et al. 2010; Furmankiewicz et al. 2011) or swarming sites (Furmankiewicz et al. 2013). Data retrieved from the automated software may

409 provide information on specific behavioural patterns like mating, mother-infant interactions and410 territoriality.

#### 411 *Conservations implications*

According to Bat Conservation International's five-year strategic plan towards bat 412 conservation, Significant Bat Areas (SBA) are areas harbouring threatened species, high 413 diversity and mega populations of bats (Bat Conservation International 2013). As referred in the 414 previous sections, automated software may be useful to generate preliminary information 415 416 regarding such areas by accounting for species richness, by detecting habitats with higher levels 417 of bat activity, or even by detecting rare or unknown sonotypes, thus suggesting the presence of cryptic bat diversity. Information on social calls and feeding buzzes retrieved by SonoChiro can 418 419 also aid in detecting roosting, foraging and mating sites, which would be of utmost importance for bat management and conservation. 420

#### 421 *Final Considerations*

There are still several gaps in the concept of applying automated identification programs 422 for bat monitoring projects, but they have some important immediate applications and a great 423 424 potential for improvement. Acoustic surveys are gradually becoming one of the main methods for monitoring and surveying bats globally considering that, in some situations, they account for 425 more species than traditional monitoring methods, and are non-invasive, which is an important 426 consideration when working with more sensitive species. Also, and perhaps more importantly, 427 passive acoustic monitoring presents a high value-for-money ratio, retrieving an immense 428 volume of information with low cost and human effort. The problem is exactly the immense 429 volume of data retrieved by this method; only by using automated software we will be able to 430 deal with terabytes of acoustic information. Technological advances might soon be able to 431

optimize automated identification programs and classifiers to make it an extremely powerful tool 432 in ecology and conservation. This also means that researchers across the world should contribute 433 434 with high-quality calls for the development of local and regional classifiers. The development of freeware, for example under the R environment, should be promoted. Indeed, more people use 435 freeware, users may be willing and able to adapt or fix the program (for example by adding calls 436 to existing libraries or by improving classification methods), and other developers may learn 437 from the program, or base new work on it. The warbleR package (Araya-Salas and Smith-438 Vidaurre 2016) which presently only aims at streamlining the analysis of animal acoustic signals, 439 may be a good starting point. In the meantime, it is important to carry out validation tests for the 440 classifiers in the available software before using them to test hypotheses or take management 441 decisions. 442

#### 443 Conclusion

The automated software programs have the potential to be used in ecological and 444 conservation studies if the variability of bat calls and more parameters are included in the 445 classifiers (Russo and Voigt 2016). The erroneous classification of species can result in 446 inaccurate distribution mapping of species or selection of incorrect areas to protect. The current 447 programs available in the market have not been tested on field data; relying on species 448 identifications made by these programs for management decision-making may thus have 449 negative conservation consequences. As of now, automated programs can and should be used to 450 make a preliminary round of identification, while files with low confidence values should 451 undergo manual confirmation, in what is called supervised automated identification. A 452 453 combination of different automated programs used with caution might be able to give a

reasonable level of accuracy but does not solve the need for efficient automated software tosample large data sets quickly.

The moderate performance of the two automated programs, namely SonoChiro and 456 Kaleidoscope Pro, in identifying bats from the Brasília National Park should not disregard the 457 ability of these programs to be used as essential tool in field of acoustics, ecology and 458 conservation. Currently, Kaleidoscope Pro can be used to filter sound files containing bat calls 459 and SonoChiro can be used to make identifications for most families and several genera. 460 Incorporation of classifiers containing highly variable bat calls from species of different regions 461 and better filters for extracting more specific call parameters can result in a powerful automated 462 tool to make rapid species identifications. 463

#### 464 Acknowledgements

465 We are grateful to Vincent Rufray for making Sonochiro available to us. We thank Frederico Hintze for providing us with the automatic identifications of bat species using Kaleidoscope and 466 Adriana Arias-Aguilar for support with the manual identifications. We would like to express our 467 gratitude to The Brazilian National Council for Scientific and Technological Development 468 (CNPq) which granted a fellow grant to L. M. S. Aguiar (309299/2016-0) and supported our 469 fieldwork through the "Cerrados do Planalto Central - Estrutura, dinâmica e processos 470 ecológicos" PELD project. 471 472 References

Typical spectrogram view of the echolocation call of Pteronotus parnelli

The y-axis is frequency in kilohertz and x-axis is time in seconds. The color scale represents the amplitude of sound in decibels (dB). The call parameters indicated are: maximum frequency (Fmax), minimum frequency (Fmin), frequency of maximum energy (FME), time duration (t), inter-pulse interval (IPI) and harmonics (HF, H2, H3, H4).

Stacked bar chart showing the level of agreement for species ( $\kappa$ =0.145, 23 agree, 579 disagree), genus ( $\kappa$ =0.326, 89 agree, 513 disagree) and family level ( $\kappa$ =0.456, 285 agree, 317 disagree). The y-axis represents the number of files analyzed.

Stacked bar chart indicating the proportion of correctly identified files for each software.

For Kaleidoscope, species = 48%, genus = 52%, family = 65% and for SonoChiro, species = 5%, genus=48% and family=77%. The y-axis shows the number of files and the x-axis is the two-automated software

An application framework to use automated acoustic identification software in ecological and conservation studies of bats.

### Table 1(on next page)

True positives, false positives, true negatives and false negatives compared to the total number of manual identifications for each of the species.

		True positives		False positives		True negatives		False negatives	
Species	Total	Kaleidoscope	SonoChiro	Kaleidoscope	SonoChiro	Kaleidoscope	SonoChiro	Kaleidoscope	SonoChiro
Cynomops sp.	31	0	0	0	0	571	571	31	31
