The Greenland Shark (*Somniosus microcephalus*) is the most common bycatch in the Greenland halibut (*Reinhardtius hippoglossoides*) bottom longline fishery in Cumberland Sound, Canada. Historically, this inshore fishery has been prosecuted through the ice during winter but winter storms and unpredictable landfast ice conditions since the mid-1990s have led to interest in developing a summer fishery during the ice-free season. However, bycatch of Greenland shark was found to increase substantially with 570 sharks captured during an experimental Greenland halibut summer fishery (i.e., mean of 6.3 sharks per 1,000 hooks set) and mortality was reported to be about 50% due to in part to fishers killing sharks that were severely entangled in longline gear. This study investigated whether the SMART (Selective Magnetic and Repellent-Treated) hook technology is a practical deterrent to Greenland shark predation and subsequent bycatch on bottom longlines. Greenland shark feeding behavior, feeding kinematics, and variables affecting entanglement/disentanglement and release are also described. The SMART hook failed to deter Greenland shark predation i.e., all sharks were captured on SMART hooks, some with more than one SMART hook in their jaw. Moreover, recently captured Greenland sharks did not exhibit a behavioral response to SMART hooks. In situ observations of Greenland shark feeding show that this species uses a powerful inertial suction mode of feeding and was able to draw bait into the mouth from a distance of 25-35 cm. This method of feeding is suggested to negate the potential deterrent effects of electropositive metal and magnetic alloy substitutions to the SMART hook technology. The number of hooks entangled by a Greenland shark and time to disentangle and live-release a shark was found to increase with body length.

29 **Abstract**

30

31 The Greenland Shark (*Somniosus microcephalus*) is the most common bycatch in the Greenland
32 halibut (*Reinhardtius hippoglossoides*) bottom longline fishery in Cumberland Sound, Canada.
33 Historically, this inshore fishery has been prosecuted through the ice during winter but winter
34 storms and unpredictable landfast ice conditions since the mid-1990s have led to interest in
35 developing a summer fishery during the ice-free season. However, bycatch of Greenland shark
36 was found to increase substantially with 570 sharks captured during an experimental Greenland
37 halibut summer fishery (i.e., mean of 6.3 sharks per 1,000 hooks set) and mortality was reported
38 to be about 50% due to in part to fishers killing sharks that were severely entangled in longline
39 gear. This study investigated whether the SMART (Selective Magnetic and Repellent-Treated)
40 hook technology is a practical deterrent to Greenland shark predation and subsequent bycatch on
41 bottom longlines. Greenland shark feeding behavior, feeding kinematics, and variables affecting
42 entanglement/disentanglement and release are also described. The SMART hook failed to deter
43 Greenland shark predation i.e., all sharks were captured on SMART hooks, some with more than
44 one SMART hook in their jaw. Moreover, recently captured Greenland sharks did not exhibit a
45 behavioral response to SMART hooks. *In situ* observations of Greenland shark feeding show that
46 this species uses a powerful inertial suction mode of feeding and was able to draw bait into the
47 mouth from a distance of 25-35 cm. This method of feeding is suggested to negate the potential
48 deterrent effects of electropositive metal and magnetic alloy substitutions to the SMART hook
49 technology. The number of hooks entangled by a Greenland shark and time to disentangle and
50 live-release a shark was found to increase with body length.

51

52

53 Introduction

54

55 Cumberland Sound is a large (ca. 250 km × 80 km) inlet located on the east coast of Baffin Island,
56 in the Arctic territory of Nunavut, Canada. Since 1986, the inshore management area of
57 Cumberland Sound has supported a small scale winter longline fishery for Greenland halibut
58 (*Reinhardtius hippoglossoides*) (DFO, 2008). The fishery was initially licensed annually under
59 experimental or exploratory licenses and has been treated as a commercial fishery since a quota of
60 500 t was established in 1994 (DFO 2008). Local interest in this fishery from the indigenous
61 community of Pangnirtung grew rapidly with peak participation (115 fishers) and landings (430 t)
62 in the early 1990s (DFO, 2008). Historically, the fishery has been prosecuted during the winter
63 (January-May) when land fast ice allows access to deep water (>400 m) which is the preferred
64 habitat of Greenland halibut (Bowering & Nedreaas, 2000; DFO, 2008). Increasingly shorter sea-
65 ice seasons, less stable ice conditions, and a winter storm in 1996 which resulted in a 70% loss of
66 fishing gear all contributed to a substantial reduction in participation and landings in the 2000s
67 with a low of six fishers and 3 t in 2007 (Dennard et al., 2010; DFO, 2008). Consequently, there
68 is an increasing interest in developing a more stable and safer summer fishery during the ice-free
69 season (July-October). Further, with the aim of developing economic and food security for Arctic
70 Canada exploratory longline surveys to determine the commercial potential of Greenland halibut
71 are proposed for the several fjords located on the east coast of Baffin Island.

72

73 The Greenland shark (*Somniosus microcephalus*) is the largest fish species in the Arctic Ocean
74 and the only species of shark to occur in Arctic waters year-round (Compagno, 1984). The
75 Greenland shark is the most common bycatch in the Cumberland Sound winter longline fishery

76 for Greenland halibut (DFO, 2008; Young, 2010). All Greenland sharks are discarded since the
77 toxicity of their flesh (MacNeil et al., 2012) precludes commercial sales. Fishers participate in a
78 voluntary logbook program and from 1987-2006, reported catches of Greenland shark in the winter
79 Greenland halibut fishery ranged from 0.4 to 2.9 sharks per 1,000 hooks (mean, 1.1/1,000 hooks)
80 (DFO, 2008). The bycatch of Greenland shark was found to increase substantially (i.e., 6.3 sharks
81 per 1,000 hooks) during an experimental longline fishery for Greenland halibut that took place in
82 Cumberland Sound during the ice-free season in 2009 (Young, 2010). During this experimental
83 fishery, a total of 570 Greenland sharks were captured incidentally. This bycatch of Greenland
84 shark was estimated to be 4.8× the biomass of Greenland halibut landed (i.e., 35 t). Greenland
85 sharks commonly entangle within longline gear and badly tangled sharks are often killed by fishers
86 (Idrobo, 2008). About 50% of the sharks captured in the 2009 experimental summer fishery were
87 released alive (Young, 2010) however post-release survival is unknown.

88

89 The International Union for the Conservation of Nature (IUCN) listed the Greenland shark as Near
90 Threatened on the basis of possible population declines and limited knowledge of life history
91 characteristics (IUCN, 2014). It has recently been suggested that Arctic populations of Greenland
92 shark are not under conservation stress (MacNeil et al., 2012). However, much of our current
93 understanding of the distribution and abundance of Greenland shark is limited to bycatch
94 information in commercial fisheries and there is an inherent danger to drawing conclusions from
95 commercial fishery data. Specifically, fisheries target aggregations of fish whose densities are
96 determined by fish behavior not abundance (Rose, 2007). In addition, recent studies suggest late
97 maturation (156 years) and extreme longevity (272 years) in the Greenland shark (Nielsen et al.,
98 2016), life history characteristics that make them highly vulnerable to overfishing. Moreover, the

99 general lack of knowledge on reproduction and factors influencing recruitment to spawning
100 biomass of Greenland sharks supports erring on the side of caution by making every effort to avoid
101 incidental harm. Sustainable resource use involves identifying ways to preserve the unique Arctic
102 ecology and there is a need to manage Greenland shark bycatch (FAO, 1999; Davis et al., 2013).

103

104 In recent years, one of the most studied methods to mitigate the bycatch of sharks in longline
105 fishing gear is the use of feeding deterrents that exploit the electrosensory system of sharks. Sharks
106 possess a complex and extensive electrosensory system comprised of the ampullae of Lorenzini
107 that are located around the snout or rostral area (Kajiura & Holland, 2002). This sensory system
108 allows sharks to detect and localize weak bioelectric fields during the final stages of prey capture
109 and they can also detect fish that are buried in sediments (Haine, Ridd & Rowe, 2001; Kalmijn,
110 1971; Kajiura, 2003; Kajiura & Holland, 2002). Demersal sharks that feed on or near the seabed
111 and at depths where visibility is limited or under conditions of total darkness (i.e., >1,000 m) are
112 more likely to rely on their olfactory, acoustico-lateralis, and electrosensory modalities. The
113 Greenland shark is distributed to depths of 2,200 m (Herdendorf & Berra, 1995) and commonly
114 exhibits a white snout caused from abrasion while foraging on the seabed suggesting it falls within
115 this group. Moreover, their relatively small eyes (Bigelow & Schroeder, 1948) and parasite
116 induced visual impairment possibly to the point of blindness in Arctic and subarctic populations
117 (Berland, 1961; Borucinska, Whiteley & Benz, 1998) suggest they may rely heavily on their
118 electrosensory system during the final stages of prey capture. Furthermore, Greenland halibut is
119 a favored prey of Greenland shark (Yano, Stevens & Compagno, 2007), it buries within bottom
120 sediments, and its depth distribution to 2,200 m (Templeman, 1973; Boje & Hareide, 1993)
121 overlaps that of the Greenland shark.

122

123 Several studies have investigated the utility of electropositive metals (EPMs) and magnets to deter
124 feeding, repel, and subsequently reduce the bycatch of sharks in longline fisheries (Brill et al.,
125 2009; Godin et al., 2013; Hutchinson et al., 2012; Kaimmer & Stoner, 2008; O'Connell et al.,
126 2010; 2011a; 2014; Rigg et al., 2009; Robbins, Peddemors & Kennelly, 2011; Stoner & Kaimmer,
127 2008; Tallack & Mandelman, 2009; Wang, McNaughton & Swimmer, 2008). There is evidence
128 to suggest that when some species of sharks enter the electromagnetic field produced by EPMs
129 and magnets they are repelled to some degree however results are mixed. It has been suggested
130 EPMs and magnets are more likely to be effective where visibility is limited (Hutchinson et al.,
131 2012) as in deep water habitats and for solitary sharks or sharks that occur at low densities and are
132 less likely to interact vigorously (O'Connell et al., 2010; Jordan, Mandelman & Kajiura, 2011;
133 Robins, Peddemors & Kennelly, 2011). However, the primary mode of feeding (i.e., ram biting
134 or suction) and ability/inability to adjust the prey capture sequence (Motta & Wilga, 2001) is also
135 likely to be an important factor determining the effect of EPMs and magnets (Hutchinson et al.,
136 2012). For example, studies suggest species that cannot readily adjust their feeding behavior
137 during the final stages of the prey capture sequence are less likely to be repelled by the
138 electromagnetic fields produced by EPMs and magnets (Hutchinson et al., 2012).

139

140 Challenges with regard to fishery applications of EPMs and magnets include the development of
141 shark deterrent technologies that have a broad between species application and limit interfering
142 with the operational and economic efficiency of commercial fisheries. By combining both an EPM
143 and magnetic alloy on the same hook the SMART (Selective Magnetic and Repellent-Treated)
144 hook has the potential to be broadly applicable to several shark species and eliminates complicated

145 baiting configurations identified as an obstacle to commercial fishery applications (Robbins,
146 Peddemors & Kennelly, 2011). In addition, the SMART hook technology has the potential to cope
147 with species-specific deterrent effects of various EPMs and magnets by facilitating selective
148 substitution once the most effective alloys have been identified. One potential limitation of this
149 technology is the small size and subsequently small effective electromagnetic field.

150

151 This study investigated whether the SMART hook is a practical technology for reducing the
152 capture of Greenland shark on bottom longlines that target Greenland halibut. Analysis included
153 capture rates in SMART hook longline experiments, in situ behavioral bioassays on the effect of
154 the SMART hook, and dissolution of the EPM component of the SMART hook. Greenland shark
155 feeding behavior on static bottom fishing gear is also described for the first time and helps to
156 provide a greater understanding of the limitations of longline feeding deterrents that exploit the
157 electrosensory system. In addition, factors influencing entanglement in longlines and time
158 required to disentangle and release Greenland sharks are also discussed.

159

160 **Materials and methods**

161

162 The current study was part of a multiyear (2011-13) gear comparison study aimed at mitigating
163 the capture of Greenland shark in Nunavut's Greenland halibut longline fisheries. SMART hook
164 longline experiments and SMART hook behavioral bioassays were conducted in Cumberland
165 Sound during the ice-free season while onboard the *RV Nuliajuk*, a 19.8 m Nunavut research vessel
166 that was crewed by experienced Greenland halibut longline fishermen. SMART hook longline
167 experiments were carried-out in August 2011 and accompanied an annual longline research survey

168 for Greenland halibut that commenced in Cumberland Sound in 2011. Variables affecting
169 entanglement and release of Greenland sharks were obtained from the 2011 experimental and
170 research survey longlines. *In situ* bioassays on the effect of the SMART hook on Greenland shark
171 behavior were carried-out on jaw-hooked sharks that were captured on standard hooks during calm
172 weather conditions. To obtain sufficient numbers of sharks, bioassays were conducted throughout
173 the multiyear gear comparison study (i.e., 2011-2013). In 2012, an archived underwater video of
174 Greenland shark feeding on bait suspended in a pot was brought to our attention. This video was
175 from an exploratory fishery for porcupine crab (*Neolithodes grimaldii*) that was carried-out in
176 subarctic waters in 1994 (He, Ennis & Walsh, 1994). This video was used in the current study to
177 describe Greenland shark feeding behavior on static fishing gear.

178

179 *Longline experiment*

180

181 Catches of Greenland shark were compared among Mustad circle 15/0 SMART hooks (20 mm
182 gap size; Figure 1) and standard Mustad circle 14/0 hooks (15.4 mm gap size). All hooks were
183 made of carbon steel and had a 0° offset. Carbon steel circle hooks are used in open water fisheries
184 for Greenland halibut with hook size ranging from 14/0 to 16/0. The SMART hook was coated
185 with Duratin(R) to resist corrosion in saltwater and specially magnetized to prevent entanglements
186 with other fishing tackle. In addition, each SMART hook was wrapped with a 0.5-0.6 g strip of
187 magnesium metal measuring approximately 250 mm × 3 mm × 0.3 mm (Figure 1).

188

189 The experimental longline consisted of 200 hooks, 100 each of the standard and SMART hooks.
190 Gangions were of braided nylon with a 118 kg breaking strength, 0.6 m in length, and attached to

191 the mainline by Mustad rotor swivels at 1.8 m intervals. To ensure equal representation of hook
192 types across the gear they were arranged in alternating groups of 20 (i.e., 20 SMART hooks, 20
193 standard hooks, etc.). All hooks were hand baited with frozen squid of similar size to that used in
194 Greenland halibut longline fisheries. To reflect the depth distribution of Greenland shark and
195 depth range of the winter and summer longline fisheries for Greenland halibut three experimental
196 longlines were set at depths of 300 m, 500 m, and 960 m. As is typical in open water commercial
197 fisheries the experimental longlines were soaked overnight with soak time ranging from 14-16 hrs.
198

199 The number of hooks used in the experimental longline (i.e., 200) was similar to the number of
200 hooks used in the Cumberland Sound winter fishery for Greenland halibut. However, longline
201 stings with many more hooks (1,000-2,500) are commonly used in open-water fisheries. Gangion
202 material, length, and interval on the experimental longlines was similar to that generally used in
203 Canada's commercial longline fisheries for Greenland halibut. However, rotor swivels which
204 prevent the gangion from becoming twisted and allow the gangion to rotate around the mainline
205 are not commonly used in Greenland halibut bottom longline fisheries. Rather, the gangion is
206 simply tied to the mainline. When Greenland shark are captured on bottom longlines they typically
207 roll resulting in the gangion and mainline wrapping around the body and caudal fin (Pike, 1994;
208 Idrobo, 2008). Rotor swivels were used in the current study in an effort to reduce the level of
209 entanglement of Greenland sharks.

210

211 Research survey longlines consisted of 200 standard Mustad circle 14/0 hooks. The bait type and
212 size as well as the gangion material, length, interval, and method of attachment to the mainline
213 (i.e., rotor swivels) were the same as the experimental longline. In 2011, a total of 22 research

214 survey longlines were hauled from overnight sets (14-16 hrs) that covered a depth range of 300-
215 1,002 m in Cumberland Sound.

216

217 A catch label was assigned to each hook upon haul back of both the experimental and research
218 survey longlines (i.e., bait present/absent, species captured, hook loss, hook entangled by shark).

219 However, only the capture of Greenland shark and number of hooks entangled by Greenland shark

220 are considered here. Greenland shark mode of capture (i.e., by jaw hook and/or entanglement),

221 number of hooks in the jaw, and time required to disentangle and release a shark were also

222 recorded. Because of their large body size, none of the Greenland sharks were hauled onboard the

223 vessel during disentanglement and all sharks were completely disentangled prior to release (i.e.,

224 there was no trailing gear embedded in or wrapped around the body or tail). It was not possible

225 however to remove hooks that were embedded in the jaw. Greenland shark were assigned to three

226 total body length size categories (<3 m, 3-4 m, and >4 m). Although poorly understood, these size

227 categories approximate the size at maturity in males (3 m; MacNeil et al., 2012) and females (>4

228 m; Yano, Stevens & Compagno, 2007).

229

230 The dissolution and fragmentation of the magnesium metal strip of SMART hooks used in the

231 longline experiment was monitored daily. Hooks that exhibited corrosion, cracking, and

232 fragmentation were recorded.

233

234 *In situ behavioral bioassays*

235

236 Tests of the ability of various EPMs and magnets to elicit a behavioral response include laboratory
237 observations on immobilized sharks, typically juveniles or small bodied adults (Stoner &
238 Kaimmer, 2008; O'Connell et al., 2011b). These tests are generally considered to provide a rapid
239 method of determining which EPM and magnetic alloys are suitable for more extensive at-sea
240 trials. During these tests sharks are inverted in the water which places them in what may be
241 considered an un-natural orientation and behavioral state (Brooks et al., 2011) that is characterized
242 by immobility and torpor. This state is called 'tonic immobility' (Watsky & Gruber, 1990). The
243 standard methodology with EPMs and magnets is to align the test material in an anterior-lateral
244 position to the head of an inverted shark, slowly move the material toward the ampullae of
245 Lorenzini, and observe the shark's behavior. Results of these behavioral bioassays have included
246 no reaction, bending away from the material laterally, and thrashing and violent arousal from tonic
247 immobility (Rice, 2008; Stoner & Kaimmer, 2008; O'Connell et al., 2011b). However, Brooks et
248 al. (2011) concluded that tonic immobility was an inherently stressful experience in juvenile lemon
249 sharks as it appeared to disrupt the short-term ventilation efficiency. Moreover, mixed results with
250 regard to deterrent effects of EPMs and magnets in laboratory behavior experiments and lack of
251 an impact on catch rates in longline experiments (Wang, McNaughton & Swimmer, 2008;
252 Kaimmer & Stoner, 2008; Brill et al., 2009; Tallack & Mandelman, 2009; Robbins, Peddemors &
253 Kennelly, 2011) suggest the possibility of a heightened response when sharks are caught off guard
254 in tonic immobility. Thus, in some situations *in situ* analysis of behavior on recently captured
255 sharks that are maintained in an upright orientation may better reflect the natural response to EPMs
256 and magnets. Moreover, placing a shark in a state of tonic immobility may not be required when
257 testing a species like the Greenland shark which has been reported to exhibit lethargic behavior

258 under natural conditions (Watanabe et al., 2012) and no resistance when captured (Bigelow &
259 Schroeder, 1948).

260

261 In the current study, the behavioral response of 14 Greenland sharks that were captured by a single
262 standard hook in the jaw and were not entangled in the longline were observed when they were
263 exposed to 1) a SMART hook (Figure 1) and 2) a 3.4 g clump of magnesium metal strips from six
264 SMART hooks that were loosely wrapped around a stainless steel clip. The clump of magnesium
265 strips was used to increase the voltage. During testing, sharks were exposed to the SMART hook
266 followed by the clump of magnesium metal strips. During each trial the test material was lowered
267 into the water on a wooden or fiberglass pole that was extended 0.75-1.25 m from the side of the
268 vessel. Subsequently, the hook or clip was slowly moved laterally to within 2-5 cm of the snout
269 of an upright shark from a distance of 0.50-0.75 m and at approximately 30° from the longitudinal
270 axis of the body of the shark. The behavior of each shark was observed and the type of response
271 recorded (i.e., no response, bend away, sudden movements of the caudal fin). All tests were
272 completed within 1-2 minutes of the shark reaching the surface of the ocean.

273

274 The voltage of the SMART hook and clump of magnesium metal strips was measured using a
275 Klein CL1000 digital multimeter (Klein Tools, Lincolnshire, Illinois). Voltage measurements
276 were obtained in seawater (34.6 ppt; 3.2°C) by connecting one electrode to the SMART hook or
277 clip of magnesium strips and the other electrode was attached to biological tissue (i.e., dorsal fin
278 clip) from a Greenland shark. This methodology is similar to that used by O'Connell et al. (2014).
279 A model IDR-309-T Gaussmeter with transverse probe (F.W. Bell, Milwaukie, Oregon) was used
280 to obtain the magnetic flux at two locations on the SMART hook (i.e., eye and point of the hook).

281

282 *Feeding behavior*

283

284 Five underwater video sequences (4:18 minutes total) of a Greenland shark interacting with a
285 baited pot were examined to determine the mode of feeding (i.e., ram bite vs. suction) and feeding
286 kinematics on static fishing gear. The shark was videotaped with a low speed (30 fields sec⁻¹)
287 Xybion ISS 255 video camera designed to perform in harsh environments including low-light level
288 underwater conditions (He, Ennis & Walsh, 1994). The camera was mounted 1.5 m above the
289 centre of a large (1.83 m × 1.83 m × 0.76 m; L×W×H) metal framed pot that was deployed on the
290 slope of the Newfoundland-Labrador Shelf (Lat. 55° 31.55' N, Long. 58° 53.23' W) at a depth of
291 878 m. Illumination was provided by a 24 W incandescent light masked with a red filter to
292 minimize the effect of light on animal behavior. The pot was baited with squid and herring that
293 was suspended on skivers.

294

295 In the video footage, the movement of suspended particles by bottom currents was used to
296 determine the approach direction (up or down current) of Greenland shark relative to the bait.
297 Dimensions of the metal frame of the pot provided a means of obtaining estimates of the length of
298 the shark and distance between the shark and the bait as the shark fed.

299

300 *Data analysis*

301

302 Greenland shark capture data from the experimental and research survey longlines were combined
303 for analysis of the effect of body size category on the number of hooks entangled by a shark and
304 time to release the shark. Tests of normality and equality of variance were performed for each

305 shark size category with the Kolmogorov-Smirnov normality test and the Levene median test,
306 respectively. When assumptions of normality and equality of variance could not be met by
307 transformation we used the non-parametric Kruskal-Wallis ANOVA on ranks. When this analysis
308 indicated significant differences among size categories a Games-Howell multiple comparison
309 procedure was used to test all pair wise comparisons. Statistical analyses were performed using
310 SPSS® Statistics Version 19 (IBM 2010). Significance level was set to 0.05.

311

312 The project was reviewed and approved by the Freshwater Institute Animal Care Committee
313 (Project # FWI-ACC-2011-045)

314

315 **Results**

316

317 *Experimental and research survey longlines*

318

319 A total of 27 Greenland sharks were captured in 2011 (Table 1). Six sharks were captured on three
320 experimental longlines (600 hooks total) and 21 sharks were captured on 22 Greenland halibut
321 research survey longlines (4,400 hooks total). Overall, sharks in the <3 m body length category
322 dominated the catches accounting for 56% of the Greenland shark captured (Table 1). The
323 SMART hook longline experiments were halted after three overnight sets owing in part to high
324 numbers of SMART hooks entangled by Greenland sharks and subsequently loss or damage of
325 hooks during disentanglement, dissolution and fragmentation of the magnesium metal strips of
326 SMART hooks, and the capture of sharks with more than a single SMART hook in the jaw. In

327 addition, results of the behavioural bioassays and observations of Greenland shark feeding
328 behaviour led to a decision to cancel additional SMART hook longline experiments in 2013.

329

330 All six of the Greenland sharks captured in the experimental longlines were captured on SMART
331 hooks. Two of these sharks had a single SMART hook in the jaw and three sharks had two
332 SMART hooks in the jaw (Table 1). Double and triple jaw hooked sharks were also captured in
333 the Greenland halibut research survey longlines (Table 1). The sixth shark captured in the
334 experimental longline did not have a hook embedded in its jaw. This shark was entangled within
335 15 hooks of a SMART hook section of the experimental longline. In addition, a Greenland shark
336 that was captured by entanglement within a research survey longline had a SMART hook
337 embedded in its jaw with a severed ganglion which is indicative of previous feeding upon a baited
338 SMART hook from an experimental longline.

339

340 The mainline was wrapped around the body and/or tail region of 13 (48%) of the Greenland sharks
341 captured in the combined experimental and research survey longlines. The number of hooks
342 entangled by these sharks ranged from 5-96 (mean, 34.4 ± 7.2 S.E.) and it required 2-20 min (mean,
343 9.8 ± 1.5 S.E.) to disentangle and release these sharks (Table 1). Entanglement of 5-96 hooks
344 corresponds to 9-173 m of mainline (mean, 61.9 ± 12.9 S.E.). During disentanglement, all hooks
345 had to be cut from the mainline and in two cases the mainline also required cutting to facilitate
346 removal of all fishing gear prior to release. Cutting of the mainline resulted in destruction of over
347 250 m of mainline. All 27 sharks were released alive and there was no evidence of external damage
348 (i.e., hemorrhaging) owing in part to the Greenland sharks thick skin. Analysis indicated body
349 length was a good predictor of the number of hooks entangled by Greenland sharks ($\chi^2_{(2)} = 23.90$,

350 $p < 0.001$) (Figure 2). Post-hoc analysis indicated the mean number of hooks entangled differed
351 significantly between all body length categories (i.e., <3 m vs 3-4 m, $p = 0.005$; <3 m vs >4 m, p
352 $= 0.009$; 3-4 m vs >4 m, $p = 0.049$). Mean time required to release a shark was also found to differ
353 significantly among body size categories ($\chi^2_{(2)} = 23.20$, $p < 0.001$) (Figure 2). In this analysis
354 release times of <1 min were standardized to a value of 1. Post-hoc tests revealed time to release
355 a shark differed significantly between all body length categories (<3 m vs 3-4 m, $p = 0.020$; <3 m
356 vs >4 m, $p = 0.003$; 3-4 m vs >4 m, $p = 0.045$).

357

358 After a single overnight set the magnesium metal strips of all SMART hooks were corroded. After
359 two overnight sets the magnesium strips were observed to be brittle and minor cracking under
360 baiting pressure. Magnesium strips on hooks subjected to three overnight sets were easily broken
361 resulting in fragments being lost under simulated baiting pressure.

362

363 *SMART hook behavioral bioassays*

364

365 The SMART hook was both electropositive and magnetic, generating 1.2 V and a magnetic flux
366 of 88 G. The clump of magnesium strips had a marginally higher voltage (1.4 V) than the SMART
367 hook. None of the 14 Greenland sharks tested exhibited a detectable change in behavior when
368 exposed to the SMART hook or clump of magnesium metal strips. These sharks were captured
369 on longlines hauled from a depth range of 600-1,125 m (mean, 841 m) and all sharks swam away
370 without delay when released. Nine of the sharks tested were <3 m in length, three were 3-4 m,
371 and two were >4 m. The behavior of all Greenland sharks captured during this study could be
372 characterized as lethargic and none of the sharks exhibited resistance whether they were hooked

373 by the mouth alone or when entangled within the longline. However, entangled sharks were
374 noticeably disoriented when released and descended well below the surface of the ocean before
375 they were observed to swim (i.e., tail beat). The calm and non-aggressive behavior of Greenland
376 shark is further illustrated by a lack of resistance by a total of 96 Greenland sharks captured during
377 our multiyear gear comparison studies (i.e., 2011-13). This includes nine sharks (i.e., five <3 m
378 in length, three 3-4 m, and one >4 m) that were captured by a single hook that was only partially
379 embedded in the skin of the upper or lower lobe of the caudal fin. These tail hooked sharks were
380 captured on longlines that were hauled back from depths of 500 to 1,125 m. Three of these tail
381 hooked sharks were captured in 2011 (Table 1).

382

383 *Feeding behavior*

384

385 Archived underwater video recordings captured images of a single large Greenland shark (3-4 m
386 in length) approaching and feeding on bait suspended in a pot. Four separate approaches were
387 recorded and the shark always approached the pot slowly and from down current. Two separate
388 feeding events were recorded with the shark oriented ventral-laterally to the camera. Feeding was
389 characterized as inertial suction. During each suction feeding event the shark approached the pot
390 slowly, rotated to align its mouth with the suspended bait, and then exhibited five to eight
391 successive suction actions over a period of approximately 20-24 sec.

392

393 The feeding kinematics were similar for each suction action. Specifically, as the lower jaw was
394 depressed the labial cartilages and upper jaw were observed to protrude anteriorly to effectively
395 form a somewhat round and laterally enclosed mouth which served to direct the suction anteriorly.

396 Each of the successive suction actions was accompanied by minor cranial elevation however the
397 timing relative to lower jaw elevation/ upper jaw protrusion was not discernable. Bulging of the
398 pharyngeal cavity was also observed during each suction action. During a suction feeding event
399 the mouth opening became larger and swelling of the pharyngeal cavity increased which appeared
400 to effectively increase the suction force. Even though the shark was outside of the pot it was able
401 to repeatedly draw the suspended bait through the mesh and into its mouth from a distance of about
402 25-35 cm. In addition, in one instance the shark was able to suck into its mouth a scavenging
403 hagfish as it swam into the path of the suction force.

404

405 It is notable that the feeding event observed in the current study was impeded by the meshes in the
406 pot. The observed shark would have ingested the prey much more quickly under natural
407 conditions. The observed feeding time is therefore longer than the period in which a foraging
408 shark would be exposed to the effects of a SMART hook.

409

410 **Discussion**

411

412 In the current study, the SMART hook did not deter Greenland shark from feeding on bottom
413 longlines. Few Greenland sharks were captured in the experimental longline yet all were captured
414 on SMART hooks and three sharks preyed upon more than one SMART hook. In addition, a
415 Greenland shark captured on a survey longline was found to have a SMART hook embedded in
416 its jaw. Additional experimental fishing trials with SMART hooks were abandoned during our
417 multiyear gear comparison study because of unfavorable results. Specifically, capture of
418 Greenland shark only on SMART hooks, repeat feeding on SMART hooks, absence of a

419 behavioral response to the SMART hook and clump of magnesium metal, fragmentation of the
420 magnesium metal strips, and powerful inertial suction which allowed a Greenland shark to suck
421 bait into its mouth from a distance of 25-35 cm. Not only do our results provide evidence that
422 Greenland sharks are not affected by the SMART hook but also that their powerful and successive
423 suction actions during a feeding event are likely to negate the deterrent effects of the SMART hook
424 technology when initiated beyond the range of the electromagnetic field produced by EPMs and
425 magnets.

426

427 Studies show that some shark species exhibit aversion responses to EPM and magnetic alloys at
428 distances of up to 100 cm, others do not respond until they are within 2 cm, while some species or
429 individuals within an effected species show no response at all (Stroud, 2008; Stoner & Kaimmer,
430 2008; Brill et al., 2009; O'Connell et al., 2010; Robbins, Peddemores & Kennelly, 2011). As
431 summarized by O'Connell et al. (2010), not all magnets and EPMs may be equally effective as
432 repellents and not all shark species or individuals within a species may respond similarly to a
433 specific alloy. Reasons for variability in repellent effects are unclear but may be related to several
434 factors including the size, shape, and type of EPM or magnetic alloy used and subsequent
435 electromagnetic field strength or how the fields are perceived by individual sharks (Brill, 2008;
436 Rigg et al., 2009; O'Connell et al., 2010).

437

438 Large (215 mm × 100 mm × 67 mm) barium-ferrite magnets with a high magnetic flux (~950 G)
439 were found to alter the *in situ* feeding and swimming behavior of suction feeding nurse sharks
440 (*Ginglymostoma cirratum*) when bait was placed within 30-50 cm of the magnets (O'Connell et
441 al., 2010). Similarly, captive juvenile sandbar sharks (*Carcharhinus plumbeus*) avoided

442 approaching closer than 100 cm to three large (100 mm × 20 mm × 20 mm) ingots comprised of
443 neodymium rare-earth magnets and highly electropositive praseodymium (Brill et al., 2009).
444 However, these large EPM and magnetic ingots would be unsuitable for use in longline fishing
445 gear. More manageable sized barium-ferrite (25 mm × 25 mm) and neodymium-iron-boride
446 magnets (25 mm × 12 mm) with a high magnetic flux (~3,850 G) have been adapted for use in
447 commercial longline and recreational hook-and-line fisheries (O'Connell et al., 2011a). However
448 varying species-specific and within species deterrent effects were observed and the complicated
449 baiting configuration would not be suitable for use in the Greenland halibut bottom longline
450 fishery.

451

452 The low magnetic flux of the SMART hook used in this study produces a relatively weak magnetic
453 field. Magnesium is a relatively weak electropositive metal however, the electric voltage produced
454 by the SMART hook was well above the nanovolt (10^{-9}) threshold of sensitivity exhibited by
455 sharks. Nevertheless, the SMART hook did not deter Greenland sharks from feeding on bottom
456 longlines. Further, none of the Greenland sharks tested during our behavioral bioassays exhibited
457 aversion behavior to the SMART hook even when the voltage was increased marginally through
458 the use of a clump of magnesium metal strips.

459

460 Stress and physical exhaustion may influence the existence and magnitude of a behavioral response
461 to EPMs and magnets. It is unclear what affect the stress of being held in captivity, netted, handled,
462 and physically inverted to induce a state of tonic immobility that appears to interfere with
463 respiration has on behavioral bioassays of sharks. In the current study, Greenland sharks were
464 captured on longlines set at depths of 600-1,125 m. Greenland shark lactate levels were recently

465 reported to increase with depth of capture on longlines (Barkley et al., 2017), but the lactate levels
466 were highly variable and baseline reference levels are unknown for this species. Moreover, many
467 of the sharks examined by Barkley et al., (2017) were entangled in the longline gear but the number
468 of individual sharks entangled, number of hooks entangled around the body and tail, or time
469 required to disentangle individual sharks prior to securing blood samples was not recorded (N.
470 Hussey, pers. comm.). Thus, it is unclear whether the elevated lactate levels were the result of
471 depth of capture or level of entanglement and time required to release sharks from longline gear.
472 We recommend future physiological and tagging studies involving the capture of Greenland shark
473 on longlines record and document whether sharks were entangled in the fishing gear, number of
474 hooks entangled, and period of time required to disentangle sharks.

475

476 All of the sharks exposed to our behavioral bioassay were hooked by the jaw alone and did not
477 appear stressed or physically exhausted as they were observed to immediately swim away from
478 the vessel when released. Conversely, entangled sharks were noticeably disoriented when released
479 and observed to descend several meters below the surface of the ocean before swimming. Because
480 Greenland sharks tend to roll and entangle in longline gear (Pike, 1994; Young, 2009; current
481 study) time of capture of sharks that are hooked by the jaw alone is likely to be shortly before haul
482 back. Moreover, it is conceivable that many of the sharks that were hooked by the jaw alone were
483 captured in the water column during haul back. For example, pelagic excursions of Greenland
484 sharks are well documented (Skomal & Benz, 2004; Stokesbury et al., 2005; Campana, Fisk &
485 Klimley, 2015), they have been captured at the surface of the ocean (Beck & Mansfield, 1969;
486 Kondyurin & Myagkov, 1982), and during our multiyear gear comparison study we observed
487 Greenland sharks at the surface of the ocean preying on Greenland halibut captured on longlines.

488 The Greenland shark belongs to the family Somniosidae commonly referred to as sleeper sharks
489 and the slow swimming, low activity level, and non-aggressive behavior of Greenland sharks is
490 well documented (Bigelow & Schroeder, 1948; Watanabe et al., 2012). Further, free swimming
491 Greenland sharks in the St. Lawrence Estuary have been described as docile during over 100 close
492 encounters with divers and their tolerance to physical contact with sport divers including being
493 captured by hook and line and lassoed by the tail has led to the development of a diver code of
494 conduct (GEERG 2009). During the current study, lack of resistance or an escape response when
495 hooked by the jaw alone or by a single hook only partially embedded in the skin of the tail and
496 ability to survive when severely entangled in longline gear suggests a high threshold of tolerance
497 and ability to cope with adverse conditions. Lastly, the calm behavior and immediate swimming
498 response upon release exhibited by all jaw hooked Greenland sharks captured on longlines during
499 our gear comparison studies leads us to suspect that stress and exhaustion had little effect during
500 our behavioral bioassays.

501

502 A reduction in the catch rates of spiny dogfish (*Squalus acanthius*) on SMART hooks in longline
503 experiments carried-out in the Gulf of Maine provides evidence of the ability of this technology to
504 deter feeding on baited hooks (O'Connell et al., 2014). Lack of evidence of a similar effect in the
505 Greenland shark may be attributed to its powerful inertial suction mode of feeding when initiated
506 beyond the range of the electromagnetic field produced by the SMART hook. It is unclear however
507 whether this would account for all capture events on SMART hooks as suction feeding may not
508 always be initiated from a suitable distance to avoid the electrosensory system from entering the
509 electromagnetic field. A high threshold of tolerance to the effects of the SMART hook may account
510 for the capture of Greenland sharks when the electrosensory system enters the electromagnetic

511 field. However, effects of EPMs and magnetic alloys on the electrosensory system of sharks and
512 rays are unclear and differing reactions among spiny dogfish and Greenland shark may be
513 attributed to how the two species perceive the electromagnetic field. For example, the trophic level
514 occupied by a shark and the diversity of predatory species in its local environment may be expected
515 to influence the perception and response to an unfamiliar stimulus. In the Gulf of Maine, a region
516 with a high diversity of species, the relatively small bodied spiny dogfish is considered to occupy
517 a trophic level of 4.0 but has a high diversity of potential predators from birth (23-29 cm) to
518 maximum length (100-120 cm) (Jensen, 1966; Nammack, Musick & Colvocoresses, 1985; Byron
519 & Morgan, 2016). Thus, spiny dogfish may be more cautious and quickly repelled when
520 encountering an unfamiliar electromagnetic field and subsequently unlikely to approach the same
521 hook again. The Greenland shark is a reported 40-100 cm at birth, grows to a length of over 600
522 cm, and is the largest fish species in the Arctic Ocean (Compagno, 1984; MacNeil et al., 2012).
523 The Greenland shark is a top predator occupying a trophic level of 4.2-5.0 in the Arctic (MacNeil
524 et al., 2012), a region of comparatively low species diversity, and apart from accounts of
525 cannibalism when captured on longlines (Borucinska, Whiteley & Benz, 1998) the Greenland
526 shark has no known predators in Canadian Arctic waters. During our longline experiments
527 Greenland sharks were only captured in the SMART hook section of the longline and the capture
528 of sharks with a SMART hook already embedded in the jaw indicates repeat feeding on SMART
529 hooks. These results and lack of a behavioral response to the SMART hook lead us to suggest not
530 only a high threshold of tolerance to the unfamiliar stimulus caused by the SMART hook but also
531 the possibility that Greenland sharks were positively stimulated by the weak electromagnetic field
532 produced by the EPM and magnetic coating on the SMART hook used in the current study.
533

534 One of the features of the SMART hook is its ability to deal with species-specific deterrent effects
535 of EPMS and magnetic coatings through selective substitution of these alloys. However, when the
536 feeding behavior observed by Greenland shark in the current study and the apparent effective range
537 of the electromagnetic fields of suitable sized EPM and magnetic alloys on other shark species is
538 taken into consideration they raise concerns with regard to the utility of SMART hook
539 substitutions. The magnetized SMART hook used in the current study possessed light weight (0.5-
540 0.6 g) and relatively weak electropositive magnesium metal strips. When the aversion response in
541 behavioral bioassays was assessed for comparatively larger ingots (70-100 g) of several types of
542 highly electropositive metals and larger (102 mm × 38 mm) high magnetic flux rare-earth magnets
543 it was found that the reactive distance of immobilized juvenile nurse sharks, lemon sharks
544 (*Negaprion brevirostris*), and spiny dogfish ranged from 2-25 cm (Rice, 2008; Stoner & Kaimmer,
545 2008; Stroud, 2008). Similarly, free swimming captive spiny dogfish and juvenile dusky
546 smoothhound sharks (*Mustelus canis*) did not exhibit a negative response to the magnetic field
547 produced by 25 mm square neodymium rare-earth magnets until they approached to within 10 cm.
548 Overall, short reactive distances are not surprising because the detection range of the ampullae of
549 Lorenzini is effective only within a few centimeters of electromagnetic fields as sharks utilize this
550 sensory system in the final stages of capture to detect weak bioelectric fields generated by their
551 prey.

552

553 To our knowledge the video of Greenland shark reported here represents the only documented
554 underwater observations of Greenland shark feeding behavior and are relevant as the shark was
555 scavenging bait from static fishing gear at the same depth longline fisheries prosecute Greenland
556 halibut. The Greenland shark exhibited inertial suction and once a suction event was initiated it

557 continued to completion. The Greenland shark was observed to exhibit several successive suction
558 actions during a feeding event. This strategy is likely to increase feeding success especially when
559 initiated from a distance in visually impaired Greenland sharks (i.e., ocular parasites) or when the
560 prey attempts to escape. The increase in gape size and increased bulging of the pharyngeal cavity
561 observed in this study would increase inertial suction forces during a feeding event and are likely
562 to increase feeding success. Stealthy cryptic approaches and powerful suction would also explain
563 how such a slow swimming shark (Watanabe et al., 2012) is able to consume Greenland halibut
564 and small seals, especially when these animals are consumed whole and with no external damage.
565 For example, stomach content analysis of a large (>4 m) Greenland shark captured on longlines
566 set through the ice in Scott Fjord, Nunavut revealed the presence of a fully intact (i.e., no external
567 wounds) and recently consumed 60 cm Greenland halibut and a fully intact 50-60 cm ringed seal
568 (*Pusa hispida*) (R. Sullivan, pers. obs.). These relatively large animals appear to have been sucked
569 directly into the large pharyngeal cavity and subsequently swallowed whole.

570

571 The Greenland shark is the largest member of the order Squaliformes or dogfish sharks which are
572 morphologically specialized for suction feeding (Motta & Wilga, 2001). Greenland sharks
573 commonly exhibit a white snout resulting from foraging on the seabed and sharks feeding on
574 organisms that live on or within the seabed commonly utilize a suction mode of feeding (Motta &
575 Wilga, 2001). Unlike ram and bite feeding sharks, suction feeders appear to have more stereotyped
576 capture events with less ability to modulate between suction and ram type feeding during the prey
577 capture sequence. Motta & Wilga (2001) proposed that suction captures will be preprogrammed
578 stereotyped bites that go to completion once initiated, regardless of the sensory input. Fast
579 swimming ram and bite feeding sharks appear to commit to attacking their prey from a distance

580 and it has been hypothesized that when they execute the feeding sequence beyond the effective
581 range of the electric field produced by EPMs the deterrent effects will be negated (Hutchinson et
582 al., 2012). Similarly, we propose that the powerful inertial suction mode of feeding exhibited by
583 Greenland shark will negate the deterrent effects of SMART hook EPM and magnetic alloy
584 substitutions suitable for use in Greenland halibut fisheries. The reactive distance by two squalid
585 shark species (nurse and spiny dogfish) to electromagnetic fields produced by several types of
586 highly electropositive metals and high magnetic flux rare-earth magnets (Rice, 2008; Stoner &
587 Kaimmer, 2008; Stroud, 2008) are within the suction range exhibited by Greenland shark in this
588 study. When feeding on longlines, we suspect Greenland sharks use their olfactory and acoustico-
589 lateralis systems to detect and orient to a bait plume and once in proximity are able to use their
590 powerful and successive inertial suction forces to pull a baited hook off the seabed at a distance
591 beyond that of the potential deterrent effects of current SMART hook technologies.

592

593 The feeding behavior of most shark species is poorly studied. This study illustrates that when the
594 primary mode of feeding is taken into consideration it can provide a better understanding of
595 potential limitations of longline feeding deterrents that exploit the electrosensory system. More
596 recently, alternate longline modifications designed to reduce the incidental capture of Greenland
597 shark have been tested with positive results (Munden, 2014). Development of methods that
598 expedite and maximize live-release of entangled Greenland sharks from longlines and studies on
599 post-release mortality will also be important to future management considerations. For example,
600 in the current study the mainline, gangions, and hooks were completely disentangled from
601 Greenland sharks prior to release. When entangled in commercial longlines, Greenland sharks are
602 often released with trailing gear that is wrapped around the body or tail (S. Grant, pers. obs.). A

603 recent study has demonstrated that when trailing fishing gear remains embedded in the tail of
604 common thresher sharks (*Alopias vulpinus*) it can lead to high post-release mortality (Sepulveda
605 et al., 2015).

606

607 The current study illustrates the degree of gear entanglement commonly caused by Greenland
608 sharks when feeding on bottom longlines. Hooks that become entangle around the tail and body
609 of the shark are unlikely to continue to lure and capture Greenland halibut (Dennard et al., 2010)
610 and considerable time and gear will be lost disentangling Greenland sharks, particularly when
611 bycatch rates are high. There is no way to determine when Greenland shark were captured during
612 an overnight set and soak time may influence Greenland shark catch rates (Pike, 1994) and the
613 degree of entanglement when sharks are captured near the seabed. Greenland shark are known to
614 move throughout the water column (Skomal & Benz, 2004; Stokesbury et al., 2005, Campana,
615 Fisk & Klimley 2015), they have been taken at the surface by harpoon and in gillnets (Beck &
616 Mansfield, 1969), and we have observed Greenland shark foraging at the surface and preying on
617 Greenland halibut captured on longlines. These observations lead us to suspect that many of the
618 Greenland sharks that are captured by a single hook in the jaw or tailfin are taken in the water
619 column during haul back of the fishing gear. Sharks entangled in the mainline were clearly
620 captured on the seabed as tension in the mainline during haul back and use of rotor swivels would
621 preclude entanglement when Greenland sharks are captured within the water column. Cyclical
622 vertical movements within the water column by the related Pacific sleeper shark (*Somniosus*
623 *pacificus*) has been hypothesized to be a foraging strategy (Hulbert, Sigler & Lunsford, 2006) and
624 adult Greenland halibut, a favored prey of Greenland shark, have been found to make regular
625 excursions several hundred meters into the water column (Vollen & Albert, 2008). As a foraging

626 strategy, vertical movements throughout the water column would help explain our observations of
627 Greenland sharks feeding near the surface and high incidence of single jaw or tail hook modes of
628 capture. If our hypothesis with regard to the pelagic capture of single jaw and tail hooked
629 Greenland sharks is correct then it would appear that smaller Greenland shark were more likely to
630 exhibit a pelagic distribution within Cumberland Sound during the ice-free season in 2011 as all
631 of the non-entangled sharks were <3 m in length (Table 1). Kondyurin & Myagkov (1982) also
632 reported a pelagic distribution for juvenile Greenland sharks that were <3 m in length. If larger
633 and sexually mature sharks are closer to the seabed during the ice-free season then there is a greater
634 likelihood they will become entangled in the fishing gear and be at greater risk of mortality.

635

636 **Conclusions**

637

638 We conclude that the SMART hook is not a suitable technology for mitigating the capture of
639 Greenland sharks on Greenland halibut bottom longlines. The SMART hook technology did not
640 deter Greenland sharks from feeding on bottom longlines and this technology did not elicit a
641 behavioral response in recently captured Greenland sharks. The Greenland shark was found to
642 exhibit a powerful inertial suction mode of feeding and was able to draw food items into its mouth
643 from a distance of at least 25-35 cm. Stealthy cryptic approaches and a powerful suction mode of
644 feeding can explain Greenland sharks consumption of seals and fish. When initiated from beyond
645 the effective range of the electromagnetic field this powerful suction is surmised to negate the
646 effect of EPM and magnetic alloy substitutions to the SMART hook technology. Fragmentation
647 of the magnesium metal strips and subsequently frequent replacement of SMART hooks is also
648 identified as a limiting factor to commercial applications.

649

650 During the current study, interactions of Greenland sharks with bottom longlines led to
651 entanglement of close to 50% of captures and at times entanglement was substantial. Even
652 severely entangled Greenland sharks were alive when hauled to the surface from depths of up to
653 1,125 m and their lethargic behavior facilitated live release efforts (i.e., removal of fishing gear).
654 Commercial longline fishers commonly release Greenland sharks with trailing gear. Post-release
655 survival of these sharks is unknown but expected to be low based on the results of related studies
656 (Sepulveda et al. 2015). Until factors influencing post-release survival of Greenland sharks are
657 better understood we recommend efforts be made to remove all trailing longline gear from
658 Greenland sharks prior to release. During the current study, we avoided cutting the mainline while
659 disentangling Greenland sharks which undoubtedly influenced the time required to release
660 individual sharks. Hence, the mean time required to disentangle and release sharks reported herein
661 is an overestimate of that expected under commercial conditions. Nevertheless, removal of trailing
662 fishing gear will be a frustrating and time consuming process when bycatch rates of Greenland
663 shark are high and sharks entangle large numbers of hooks. Further, economic costs associated
664 with damage to and loss of fishing gear exemplifies the need to continue to investigate
665 modifications to fishing gear, potential gear substitutions, or spatial management of fishing effort
666 to reduce the incidental capture of Greenland sharks.

Figure 1

A circle 15/0 SMART hook (source: S. Grant).

Figure 2 (on next page)

Box plots.

A) Number of hooks entangled by Greenland sharks and B) time to release sharks for three body length categories (<3 m, n=15; 3-4 m, n=6; >4 m, n=6).

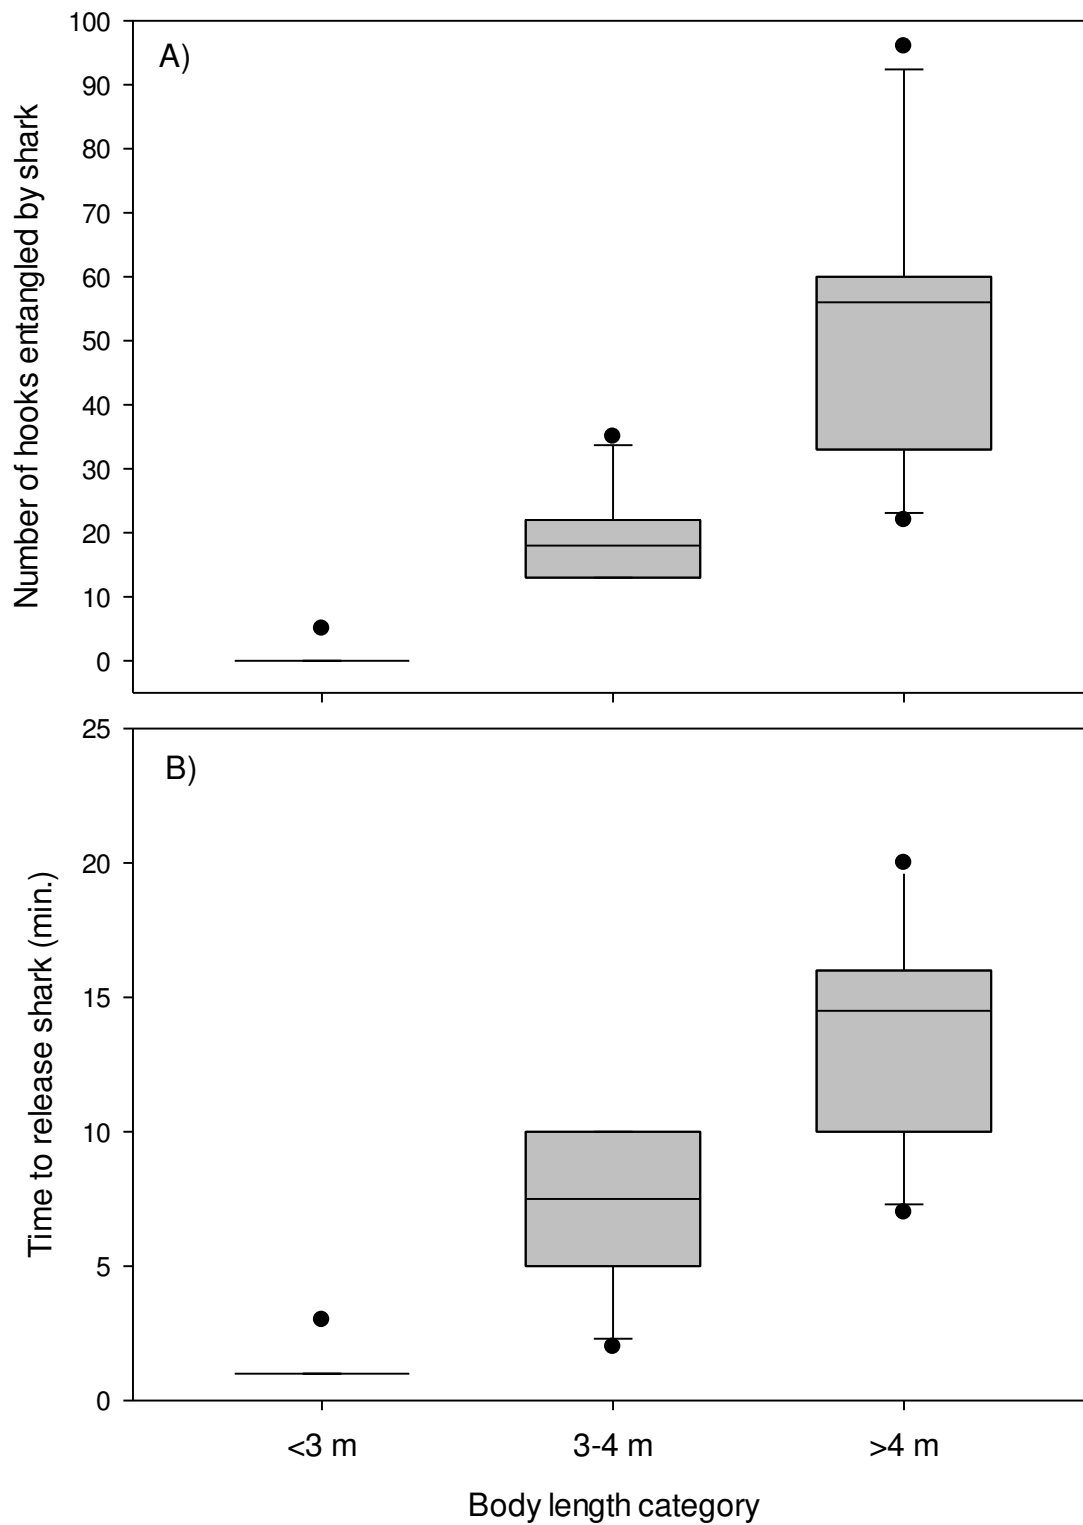

Table 1 (on next page)

Greenland shark catch summary in experimental and survey longlines.

1

Longline type	Hook type	Number of hooks in jaw	Length category	Number of hooks entangled	Time required to release shark (min)
Experimental	SMART	1	<3 m	0	<1
	SMART	0 ^a	3-4 m	15	10
	SMART	1	3-4 m	35	5
	SMART	2	>4 m	33	15
	SMART	2	>4 m	96	14
	SMART	2	>4 m	52	16
Survey	Standard	0 ^b	<3 m	0	<1
	Standard	0 ^b	<3 m	0	<1
	Standard	0 ^b	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	1	<3 m	0	<1
	Standard	2	<3 m	0	<1
	Standard	3	<3 m	5	3
	Standard	1	3-4 m	13	5
	Standard	1	3-4 m	13	10
	Standard	1	3-4 m	22	10
	Standard	3	3-4 m	21	2
SMART	1 ^c	>4 m	60	7	
Standard	2	>4 m	22	10	
Standard	2	>4 m	60	20	

2

3 ^a entangled in SMART hook section of experimental longline.4 ^b captured by single hook partially embedded in skin of tail.5 ^c shark captured by entanglement in survey longline but SMART hook embedded in jaw.
