Factors controlling the spread of invasive earthworms in Minnesota's Boundary Waters Canoe Area Wilderness are poorly known. Believed to have been introduced by anglers who use them as bait, invasive earthworms can alter the physical and chemical properties of soil and modify forest plant communities. To examine factors influencing earthworm distribution and abundance, we sampled 38 islands across five lakes to assess the effects of campsites, fire, and entry point distance on earthworm density, biomass and species richness. We hypothesized that all three parameters would be greater on islands with campsites, lower on burned islands, and would decrease with distance from the wilderness entry point. In addition to sampling earthworms, we collected soil cores to examine soil organic matter and recorded ground and vegetation cover. Campsite presence was the single most important factor affecting sampled earthworm communities; density, biomass and species richness were all higher on islands having campsites. Fire was associated with reduced earthworm density, but had no direct effects on earthworm biomass or species richness. Fire influenced earthworm biomass primarily through its negative relationship to groundcover and through an interaction with entry point distance. Distance affected density but no other factor. For islands with campsites, however, distance from the entry point had a counterintuitive effect in that earthworm biomass, which increased with entry point distance.

20 Abstract

21 Factors controlling the spread of invasive earthworms in the forest ecosystems of
22 Minnesota's Boundary Waters Canoe Area Wilderness are poorly known. Believed to have been
23 introduced by anglers who use them as bait, invasive earthworms can alter the physical and
24 chemical properties of soil and modify forest plant communities. To examine factors influencing
25 earthworm distribution and abundance, we sampled 38 islands across five lakes to assess the
26 effects of campsites, fire, and entry point distance on earthworm density, biomass and species
27 richness. We hypothesized that all three parameters would be greater on islands with campsites,
28 lower on burned islands, and would decrease with distance from the wilderness entry point. In
29 addition to sampling earthworms, we collected soil cores to examine soil organic matter and
30 recorded ground and vegetation cover.

31 Campsite presence was the single most important factor affecting sampled earthworm
32 communities; density, biomass and species richness were all higher on islands having campsites.
33 Fire was associated with reduced earthworm density, but had no direct effects on earthworm
34 biomass or species richness. Fire influenced earthworm biomass primarily through its negative
35 relationship to groundcover and through an interaction with entry point distance. Entry point
36 distance itself affected density, and through an inaction with campsite presence, earthworm
37 biomass as well. For islands with campsites, earthworm biomass increased as distance from the
38 entry point increased.

39

40 Introduction

41 Following the end of the last glaciation 12,000 years ago, northern forests of the present-
42 day United States were believed to have been entirely free of earthworms (Tiunov et al., 2006).
43 Since the glacial retreat, native earthworm populations have largely remained below the glaciers'
44 southern terminus, but in recent times non-native earthworms from Europe have proliferated and
45 become increasingly common on old glaciated landscape (Callaham et al., 2006; Hopfensperger
46 & Hamilton, 2015). As non-native earthworms expanded their range north, they have profoundly
47 impacted the northern forest ecosystems that evolved in their absence (Hale, Frelich & Reich,
48 2005; Frelich et al., 2006). Many earthworms feed on leaf litter and decomposing plant material
49 that accumulates as a spongy layer of duff on the forest floor. The duff layer provides habitat for
50 ground-dwelling animals and understory vegetation and helps prevent soil erosion. Earthworms
51 consume the duff and excrete nutrient-rich castings, which in combination with their bioturbation
52 and mixing of soil layers, can stimulate microbial activity and greatly accelerate soil nutrient
53 cycling (Bohlen et al., 2004a). Although these processes benefit horticultural and agricultural
54 systems (Bertrand et al., 2015; Sharma, Tomar & Chakraborty, 2017), they can fundamentally
55 alter the functioning of northern forest ecosystems (Bohlen et al., 2004b). Among other
56 detrimental effects, earthworms can alter forest seed banks, kill plant roots, and increase soil
57 compaction, which can lead to increased erosion and nutrient leaching (Costello & Lamberti,
58 2009; Hopfensperger, Leighton & Fahey, 2011; Drouin et al., 2014; Nuzzo, Davalos & Blossey,
59 2015), and negatively affect native flora and fauna (Hale et al., 2008; Loss & Blair, 2011;
60 Fisichelli et al., 2013; Dobson & Blossey, 2015).

61 Non-native earthworms are common in the Boundary Waters, a vast wilderness region of
62 interconnected lakes straddling the Canada–United States border between Ontario and Minnesota
63 (Fig. 1). In northern Minnesota this region has been designated the Boundary Water Canoe Area

64 (BWCA) Wilderness. Known for its pristine lakes and excellent sports fishing, the BWCA has
65 long been a destination for anglers (Heinselman, 1999), and it is probable that anglers played an
66 important role in spreading non-native earthworms into the area by using them as fish bait
67 (Cameron, Bayne & Clapperton, 2007; Hale, 2008; Kilian et al., 2012). Non-native earthworms
68 such as “night crawlers” (*Lumbricus terrestris*) and “red wigglers” (*Lumbricus rubellus* or
69 *Dendrodrilus rubidus*) have been sold as fishing bait for decades and are now abundant in
70 Boundary Waters forests. It is not unusual for anglers to dump unused bait (Keller et al., 2007;
71 Frelich & Reich, 2009), and the bait containers contain not only adult earthworms, but also soil
72 that could potentially harbor earthworm cocoons. Campsites are likely dumping grounds for
73 unused bait and probable points of earthworm invasion because visitors to the BWCA are
74 required to stay at designated campsites.

75 While earthworms are novel to the Boundary Waters, fire has shaped the region for
76 millennia (Heinselman, 1999). Historically, fire disturbance occurred at 50-100-year intervals,
77 but fire suppression practices over the past century have increased fire intervals to 700 years or
78 more (Heinselman, 1999; Frelich & Reich, 2009). Forest fire frequency could matter to
79 earthworms because burning away duff and litter layers has the potential for controlling their
80 numbers (Callaham et al., 2003). Fire kills adults that inhabit the leaf litter (i.e., epigeic species)
81 and may reduce the viability of earthworm cocoons in the soil (Ikeda et al., 2015). For soil-
82 dwelling and deep-burrowing earthworms (i.e., endogenic and anecic species), burning away the
83 duff and litter layers would limit food resources, likely starve earthworms, and reduce their
84 fitness (Callaham & Blair, 1999; Coyle et al., 2017). Despite its potential for earthworm control,
85 only a handful of studies have examined how fire affects earthworm dynamics in North
86 American ecosystems (James, 1982; 1988; Callaham & Blair, 1999; Callaham et al., 2003; Ikeda

87 et al., 2015), and fewer still have examined earthworm responses to fire in northern forests
88 (Frelich et al., 2006).

89 To assess the role of campsites and forest fires in influencing the distribution and
90 abundance of non-native earthworms in the BWCA, we examined lake islands that either had or
91 did not have campsites and were either burned or not burned by the Pagami Creek Fire of 2011.
92 Earthworm abundance was measured in terms of earthworm density, biomass and species
93 richness. We studied islands because they constitute discrete forest patches separated by water
94 that could be characterized as having one condition or the other for each variable (i.e., campsites
95 present/absent, burned/not burned). The islands sampled were located along a chain of
96 interconnected lakes that bordered the northern edge of the 2011 Pagami Creek Fire (Fig. 1).
97 Canoe access for this lake chain is largely limited to a single entry point on Lake One at the west
98 end of the chain. This isolated entry allowed us to examine how distance from the source pool –
99 i.e., arriving anglers carrying earthworm bait – affected earthworm abundance across the islands
100 examined.

101 We hypothesized that islands with campsites would have more earthworms than those
102 without because campsites would receive multiple earthworm introductions from anglers
103 dumping unused bait in or near the campsite (Novo et al., 2015). By contrast, islands that were
104 burned would have fewer earthworms than those not burned because decreased duff and litter on
105 the forest floor, reduced soil organic matter, and decreased leaf litter inputs from trees and
106 vegetation would decrease food availability, thereby limiting earthworm growth and fecundity.
107 Islands having the greatest number of earthworms, therefore, would be those that had campsites
108 and were not burned, whereas those having the least would be burned and without campsites. We
109 also hypothesized that earthworm density and biomass would decrease as distance from the entry

110 point increased. We assumed campsites closest to the entry point would have higher visitation
111 rates because day and weekend anglers would be less likely to travel far into the wilderness
112 (Lime, 1971). Hypotheses about relationships between variables and earthworm biomass are
113 summarized in Fig. 2.

114

115 **Field-Site Description**

116 The 4410 km² BWCA Wilderness is located in Minnesota's Superior National Forest
117 (47°57' N, 91°48' W) and extends 185 km along the Minnesota/Ontario border (Fig. 1, inset).
118 Designated as a wilderness area in 1978, the area contains approximately 1175 glacial lakes and
119 hundreds of kilometers of rivers and streams (Heinselman, 1999). It is the largest Forest Service
120 Wilderness area east of the Rocky Mountains and the most heavily used wilderness in the United
121 States, with over 150,000 overnight and day-use visitors annually (Eagleston & Marion, 2017).
122 Lakes and waterways comprise approximately 20% of the Boundary Waters wilderness and
123 cross-country canoe travel is made possible by a network of portage trails that connect lakes.
124 Forests in the BWCA are a mixture of conifers and hardwoods that include various species of
125 pine (*Pinus banksiana*, *P. resinosa*, and *P. strobus*), white cedar (*Thuja occidentalis*), balsam fir
126 (*Abies balsamea*), white spruce (*Picea glauca*), and hardwoods such as paper birch (*Betula*
127 *papyrifera*), big-toothed aspen (*Populus grandidentata*) and white oak (*Quercus alba*) (Dickens,
128 Gerhardt & Collinge, 2005)

129 The climate of the BWCA region is hemiboreal with mild/cool summers and long winters
130 (Köppen classification Dfb). Average July and January temperatures are 20° and -11° C,
131 respectively, with temperature extremes of 32° and -40° C occurring (Dickens et al., 2005).
132 Annual precipitation ranges 66-78 cm and occurs mostly in winter as snow (ca. 40%). Soils of

133 the area are thin and acidic and overlay Canadian Shield bedrock. Charcoal is almost universal in
134 upper soil layers, indicative of the key role fire has played in shaping this ecosystem
135 (Heinselman, 1999).

136 Recreational access to the BWCA is controlled through a permit-based quota system that
137 limits the number of people entering through each wilderness entry point. Visitors can obtain
138 permits from May thru September and group sizes are limited to nine. Camping is restricted to
139 approximately 2000 designated campsites established by the by U.S. Forest Service, that are
140 unambiguously indicated by cast iron fire grates located at each site (Eagleston & Marion,
141 2017a).

142

143 **Material & Methods**

144 On 9 July 2016 we put in canoes at BWCA entry point 30 on Lake One and headed east
145 along a route that skirted the northern edge of the 2011 Pagami Creek Fire (Fig. 1). Over 7 d we
146 sampled 38 islands on lakes One, Two, Three, Four, Hudson and Insula. Islands were selected on
147 the basis of their fire history (burned/not burned) and the presence/absence of campsites (Table
148 1). Island selection was made using maps showing campsite locations (Fisher map F4) and the
149 area covered by the Pagami Creek Fire (USDA Pagami Creek Fire Map). Initial selection
150 followed a balanced design for each combination of characteristics (i.e., burned/campsite,
151 burned/no campsite, not burned/campsite, not burned/no campsite). However, field sampling
152 revealed islands marked as burned were not, and some campsites on burned islands could not be
153 found. Consequently, these islands were discarded from our sample set and resulted in an
154 unbalanced design.

155 Distances between islands and the entry point were examined using straight-line
156 distances instead of hypothetical canoe travel distances because the latter can be highly variable.
157 Canoeists and anglers need not follow direct pathways between lakes and islands, and side trips
158 to explore fishing spots and campsite locations are common. Also, multiple pathways may exist
159 for reaching islands, especially in geographically complex lakes such as Insula. Thus,
160 determining actual travel routes becomes a problematic exercise whereas straight-line distances
161 are easily made and independent of human choice.

162 Sampling islands followed a standard procedure: Upon reaching an island, its burn
163 condition, campsite status and GPS coordinates were recorded. Following this, three sampling
164 sites spaced equidistantly around the island's perimeter and approximately 10 m inland were
165 chosen using three criteria: 1) site accessibility from shore, 2) availability of flat and open
166 ground, and 3) lack of dense underbrush allowing easy access to the ground for sampling. After
167 reaching a site, a center point was established and the percent of understory vegetation cover and
168 percent of exposed soil was estimated within a 1 m radius of the site center. Visual estimates of
169 cover and exposure were made with the aid of a chart depicting the Braun-Blanquet percent
170 cover classes. Percent exposed soil was converted into percent groundcover by subtracting
171 values from 100. To assess soil organic matter, three soil cores were collected within the
172 established 1 m radius. The upper 10 cm of each 2.5 cm diameter core was collected and
173 combined in a plastic bag for later organic matter analysis in the lab.

174 Earthworms were sampled following the procedures outlined in Hale (2013). A mustard
175 water solution was prepared by combining 240 ml of powdered mustard with 4 L of water. This
176 solution acts as an irritant that when poured on the ground and allowed to soak into the soil
177 causes earthworms to emerge as they attempt to avoid the mustard. Half of this mustard solution

178 was poured inside a 0.2 m² quadrat placed at the site's center and emerging earthworms were
179 collected with forceps and placed in 50 ml plastic centrifuge tubes. After 2 minutes, the
180 remaining solution was poured into the quadrat and earthworms were collected until they
181 stopped emerging. This procedure was repeated at each site and earthworms from all three sites
182 were combined for each island and preserved in a solution of 70% isopropyl alcohol and 2%
183 formalin. Field conditions made it impractical to clear earthworm guts prior to preservation.
184 Back in the laboratory, earthworms were identified using Hale (2013) and counted. Worms from
185 each site were then combined, dried and weighed to determine biomass.

186 We used the loss-on-ignition method to determined soil organic matter. Soil was dried in
187 an oven at 40° C for 7 days, then homogenized with mortar and pestle. Homogenized samples
188 were put into pre-weighed porcelain crucibles and weighed, then ignited in a muffle-furnace
189 (Fisher Scientific Isotemp Muffle Furnace Model 550-126) at 550° C for 3 h. The samples were
190 subsequently cooled, placed in a desiccator overnight, and then weighed to the nearest 0.001 g so
191 biomass could be calculated.

192

193 **Statistical analyses**

194 To examine the effect of campsite presence, fire history and entry point distance on
195 earthworm richness, density and biomass, we used General Linear Models (GLM). A Structural
196 Equation Modelling (SEM) was used to us examine relationships between earthworm biomass
197 and the variables included in the metamodel (Fig. 2).

198 GLMs for each response variable were performed using JMP 8.0.1 (SAS Institute Inc.,
199 2009). Models used a Poison distribution to fit variables and a log link function to create linear

200 models. Chi-squared (X^2) probabilities ascertained significance levels of individual factors and
201 interactions. We started with a full model that included main factor effects and all interactions,
202 but three-way interactions were not significant and discarded from final models. We chose not to
203 use a nested design (i.e., islands nested within lakes) because BWCA lakes may be arbitrarily
204 defined. Lakes in the Boundary Waters are often interconnected and multiple lakes may be
205 combined under one name, or alternatively, a single lake may be divided into multiple lakes. For
206 example, Lake Insula is comprised on many small “lakes”, whereas Lake Three and Lake Four
207 are two sections of the same lake (Fig. 1).

208 The SEM was created in AMOS 16 (Amos Development Corporation, 2007) and used to
209 examine direct and indirect relationships between earthworm biomass and fire history, entry
210 point distance, understory plant cover, groundcover, and soil organic matter. We used four
211 indices to assess the fit of the SEM to avoid bias from any one index (Hintz & Lonzarich, 2018).
212 A chi-square test evaluated the consistency of the data with p-values greater than 0.05 specifying
213 good fit (Grace et al., 2010). To evaluate model fit we looked at the goodness-of-fit index (GFI),
214 standardized root mean square residual (SRMR), and root mean square error of approximation
215 (RMSEA). GFI values greater than 0.90 and SRMR and RMSEA values below 0.08 indicate
216 good fit (Hooper, Couglan & Mullen, 2008; Hu & Bentler, 1999).

217

218 **Results**

219 We sampled 38 islands across the six connecting lakes, of these, 12 were burned and 13
220 had campsites (Fig. 1, Table 1). Island size ranged from 0.4 to 11.8 ha and straight-line distances
221 from the entry point ranged between 3.4 and 26.3 km. Earthworms occurred on all but two of the

222 sampled islands. Mean (± 1 SE) earthworm biomass and density across islands was 12.2 ± 2.5 g
223 m^{-2} and 27.2 ± 3.5 individuals m^{-2} , respectively.

224 Eight earthworm species were identified (Table 2), of which *Dendrobaena octaedra*
225 (Savigny 1826) and *Lumbricus rubellus* (Hoffmeister 1843) were most common. Species
226 richness on islands averaged 1.95 species. Juvenile *Lumbricus* spp. were the most frequently
227 encountered taxonomic group and many of these juveniles were likely *L. terrestris* (Linnaeus
228 1758); however, their developmental stage precluded positive identification. Campsite presence
229 was the sole factor affecting earthworm species richness ($X^2 = 4.13$, $df = 1$, 37 ; $p = 0.04$), with
230 campsite-bearing islands averaging 1.13 more species than those without.

231 Campsite presence and burn history had important effects on earthworm abundance.
232 Campsite presence was the only factor that affected both earthworm biomass and density (Table
233 3). The effect on biomass was greater, with campsite-bearing islands having 81% more
234 earthworm biomass as compared to islands lacking campsites. By comparison, earthworm
235 density on campsite-bearing islands increased by only 37%. Fire was associated with reductions
236 in earthworm density, but not biomass (Table 3, Fig. 3). Earthworm density also responded to a
237 Burned*Campsite interaction such that burned, campsite-bearing islands had approximately half
238 the density of non-burned, campsite-bearing islands (Fig. 3A). Islands without campsites had
239 comparable earthworm densities regardless of burn history.

240 Distance from the entry point directly influenced earthworm density and had interactive
241 effects with campsite presence and burn history on earthworm biomass (Table 3). Across islands,
242 earthworm density showed a significant decrease as entry point distance increased. By contrast,
243 earthworm biomass increased with entry point distance for campsite-bearing islands while
244 remaining unchanged for islands without campsites (i.e., the Campsite*Distance interaction

245 shown in Fig. 3A). There was also a Distance*Burned interaction such that earthworm biomass
246 decreased as distance from the entry point increased on burned islands, whereas non-burned
247 islands showed the opposite trend (Fig. 3B).

248 Our SEM (Fig. 5) showed a good fit to the data with a high GFI (0.96), low SRMR (0.08)
249 and RMSEA (0.00), and a non-significant chi-square ($X^2 = 6.32$, $df = 9$, $p = 0.71$). Overall, the
250 model explained 47% of the variation in earthworm biomass found on BWCA islands.

251 SEM analysis broadly corroborated the results of the GLM in that both models showed
252 that campsite presence was the most important single factor affecting earthworm biomass. The
253 SEM showed that entry point distance had a direct and positive relationship with earthworm
254 biomass whereas fire exerted its influence through other factors. Fire was associated with less
255 groundcover and soil organic matter, but more understory plant cover. Of these three factors,
256 only groundcover affected earthworm biomass. Groundcover had a positive relationship to
257 earthworm biomass whereas soil organic matter and understory plant cover showed none.
258 Understory plant cover was also positively correlated to earthworm biomass.

259

260 **Discussion**

261 We hypothesized that earthworms would be more abundant on islands with campsites,
262 less abundant on those that had burned, and would decrease as distance from the entry point
263 increased. The data provide strong support for the first hypothesis (campsites), partial support for
264 the second (burn history), and little support for the third (entry point distance).

265 Whether measured in terms of biomass or density, earthworms were consistently more
266 abundant on islands with campsites as compared to those without. This result corroborates the

267 findings of previous studies showing that human activity influences the distribution and
268 abundance of non-native earthworms (Hendrix et al., 2008). These include correlations with road
269 proximity (Cameron & Bayne, 2009) and boat launches (Cameron, Bayne & Clapperton, 2007),
270 and their spread through use as fish bait (Keller et al., 2007). That wilderness campsites may be
271 important points of invasion for non-native species is often overlooked in studies of campsite
272 impacts (e.g., Monz, Pickering & Hadwen, 2013; Eagleston & Marion, 2017a; Marion et al.,
273 2016), despite the fact that campsites are where people leave behind food wastes (a potential
274 source of seeds), and may inadvertently transport seeds and other propagules on clothing,
275 footwear or camping equipment (Ansong & Pickering, 2013; Eagleston & Marion, 2017b).
276 Campsites might be construed, therefore, as nodes in a distribution network facilitating the
277 spread of exotic species across wilderness areas. This may be especially true in the BWCA
278 because nearly all travel is done by canoe, which makes established campsites and canoe
279 portages (Dickens et al., 2005) the main points of contact between visitors and the wilderness
280 landscape.

281 Fire effects were not as prominent as campsite effects. Although burned islands did have
282 lower densities of earthworms as predicted, earthworm biomass and richness were unaffected.
283 Fire can kill epigenic species that live in the litter (Ikeda et al., 2015), but is less likely to affect
284 endogenic and anecic species that burrow into the soil. Fire increases soil temperatures only a
285 few degrees near the surface, and just a few centimeters below the temperatures remain
286 unchanged (Ikeda et al., 2015). Rather than killing worms directly, we expected fire to exert
287 influence through its effects on ground cover and soil organic matter, and through understory
288 vegetation, decreasing the former two and increasing the latter. Our SEM showed that fire had

289 the predicted effects these three variables, but only groundcover had a significant effect on
290 earthworm biomass such that where litter was abundant, so was earthworm biomass.

291 Less clear is why understory vegetation responded positively to earthworms. Numerous studies
292 have shown that earthworms invading northern forests typically cause understory vegetation to
293 decline (see Bohlen et al., 2004b for review). Earthworms can consume newly germinated
294 seedlings (Drouin et al., 2014), the fine roots of plants (Gilbert et al., 2014), and alter the soil
295 microflora to favor only certain species (Drouin, Bradley & Lapointe, 2016). Of course,
296 earthworms can have beneficial effects, as is seen in horticultural and agricultural systems
297 (Bertrand et al., 2015; Sharma, Tomar & Chakraborty, 2017), but why these benefits would
298 occur on islands and not in other areas of the BWCA is outside the scope of our study.

299 The most perplexing result of our study was the positive relationship between entry point
300 distance and earthworm biomass. Our prediction was that earthworm biomass would *decrease* on
301 islands further away from the entry point, and this was based on the assumption that discarding
302 unused earthworm bait would be more frequent in areas of high human traffic closer to the entry
303 point. We reasoned that weekend anglers do not travel far from entry points and bait dumping
304 would become less frequent further away as angler traffic diminished. Of course, our
305 assumptions about human behavior may be wrong. We speculate that anglers may actually be
306 *less* likely to dispose of worms if they are fishing for only short time. In a survey of Wisconsin
307 and Michigan boat owners, Keller et al. (2007) reported that 65% of anglers saved leftover
308 earthworm bait for future fishing trips as opposed to 41% who disposed of them on land or in
309 trash. Similar results were found by Kilian et al. (2012) in their survey of Maryland anglers.
310 Earthworms are sold in soil-packed containers and can be kept alive for weeks under cool and
311 moist conditions (Sherman, 2003). If bait containers are exposed to long days in a sunlit canoe,

312 however, their viability may be compromised. Desiccating soil and temperatures exceeding 30°
313 C can kill earthworms (Berry & Jordan, 2001), and we speculate that multi-day canoe trips are
314 likely to have higher bait mortality than day or weekend trips. Rather than pack out dead and
315 dying worms, long-distance anglers may choose to dump bait containers enroute as they pass
316 through the wilderness. Even if adult earthworms in containers are dead, the soil in which they
317 were kept could contain earthworm cocoons. Whether or not this practice actually occurs would
318 require further study, yet it highlights the need for understanding human behavior for managing
319 the spread of earthworms in the BWCA (Eagleston & Marion, 2017a; 2017b; Marion et al.,
320 2016).

321

322 **Conclusion**

323 Earthworms are often called ecosystem engineers because of the multitudinous effects
324 they have on soils, nutrient cycling, and plants and animals (Holdsworth, Frelich & Reich, 2007;
325 Eisenhauer, 2010). Their presence can profoundly alter ecosystems and their invasion into
326 wilderness areas presents a challenge to resource managers charged with maintaining these
327 natural systems in a state similar to what they were pre-European settlement (Blouin et al.,
328 2013). Our investigation of how campsites, fire, and entry point proximity influence earthworm
329 abundance in the BWCA may have management implications. Our data support the hypothesis
330 that campsites are key points of invasion, and suggest that fire may lower earthworm densities
331 via its influence on worm food resources (e.g., litter and duff). Our data also indicate that the
332 distance from a wilderness entry point can influence the distribution and abundance of invasive
333 worms, and these effects may be best understood in the context of campsite use behaviors and
334 bait use practices. We recommend that resource managers promote “leave no trace” principles

335 emphasizing the environmental risks posed by invasive species; for example, by incorporating
336 this message in videos visitors are required to watch before entering the BWCA (Guo et al.,
337 2017). As part of their public education efforts, managers might also consider bait container
338 warning labels that include instructions on the proper earthworm disposal after use. These
339 actions may slow the spread of earthworms in the BWCA and other wilderness areas; however,
340 removing these ecosystem engineers from invaded regions is problematic at best, if not
341 impossible (Shartell et al., 2015). Once introduced, earthworms become part of the ecosystem
342 (Bohlen et al., 2004b), and efforts directed at learning ways to mitigate their impacts will likely
343 become as important as trying to control their spread (Tammeorg et al., 2014).

344

345

346 **Acknowledgements**

347 We wish to thank Wil Raasch for his contributions to the work, and David Lonzarich for his
348 assistance with the SEM analysis.

Table 1 (on next page)

Physical characteristics of the 38 sampled islands.

“X”s indicate that islands were burned by the Pagami Creek Fire or had a campsite. Entry distance is the linear distance from BWCA entry point 30 on Lake One (see Fig. 1), Island Size is the area of the island.

1 **Table 1.**

Table 3 (on next page)

Effects of campsites, fire and entry point distance on earthworm biomass and density.

Results of the two General Linear Models used to examine earthworm biomass (g m^{-2}) and density (individuals m^{-2}) in relation to burn history (Burned), campsite presence (Campsite) and linear distance from the BWCA entry point (Distance), as well as interactions among these factors ($df= 1, 36$). Bold font indicates significant p-values. Whole model statistics: X^2 density = 45.30, $df= 6, 31$, $p < 0.0001$; X^2 biomass = 84.23, $df= 6, 31$, $p < 0.0001$.

1

2 **Table 3.**

3

Factor	Biomass		Density	
	<i>X</i>²	P-value	<i>X</i>²	P-value
Burned	0.67	0.413	8.51	0.004
Campsite	27.82	<0.001	4.92	0.027
Distance	0.45	0.500	17.01	<0.001
Burned*Campsite	0.19	0.665	13.74	<0.001
Campsite*Distance	5.32	0.021	1.25	0.26
Distance*Burned	6.41	0.011	2.19	0.14

Figure 1(on next page)

Study location.

Map shows the location of the Boundary Waters Canoe Area Wilderness in northern Minnesota (inset) and the study area (small white rectangle), which has been enlarged to show the six connecting lakes (One, Two, Three, Four, Hudson and Insula) and the 38 islands that were sampled (shown in black). The dotted line represents the northern extent of the 2011 Pagami Creek Fire; the area south of the line was burned by the fire.

Figure 1

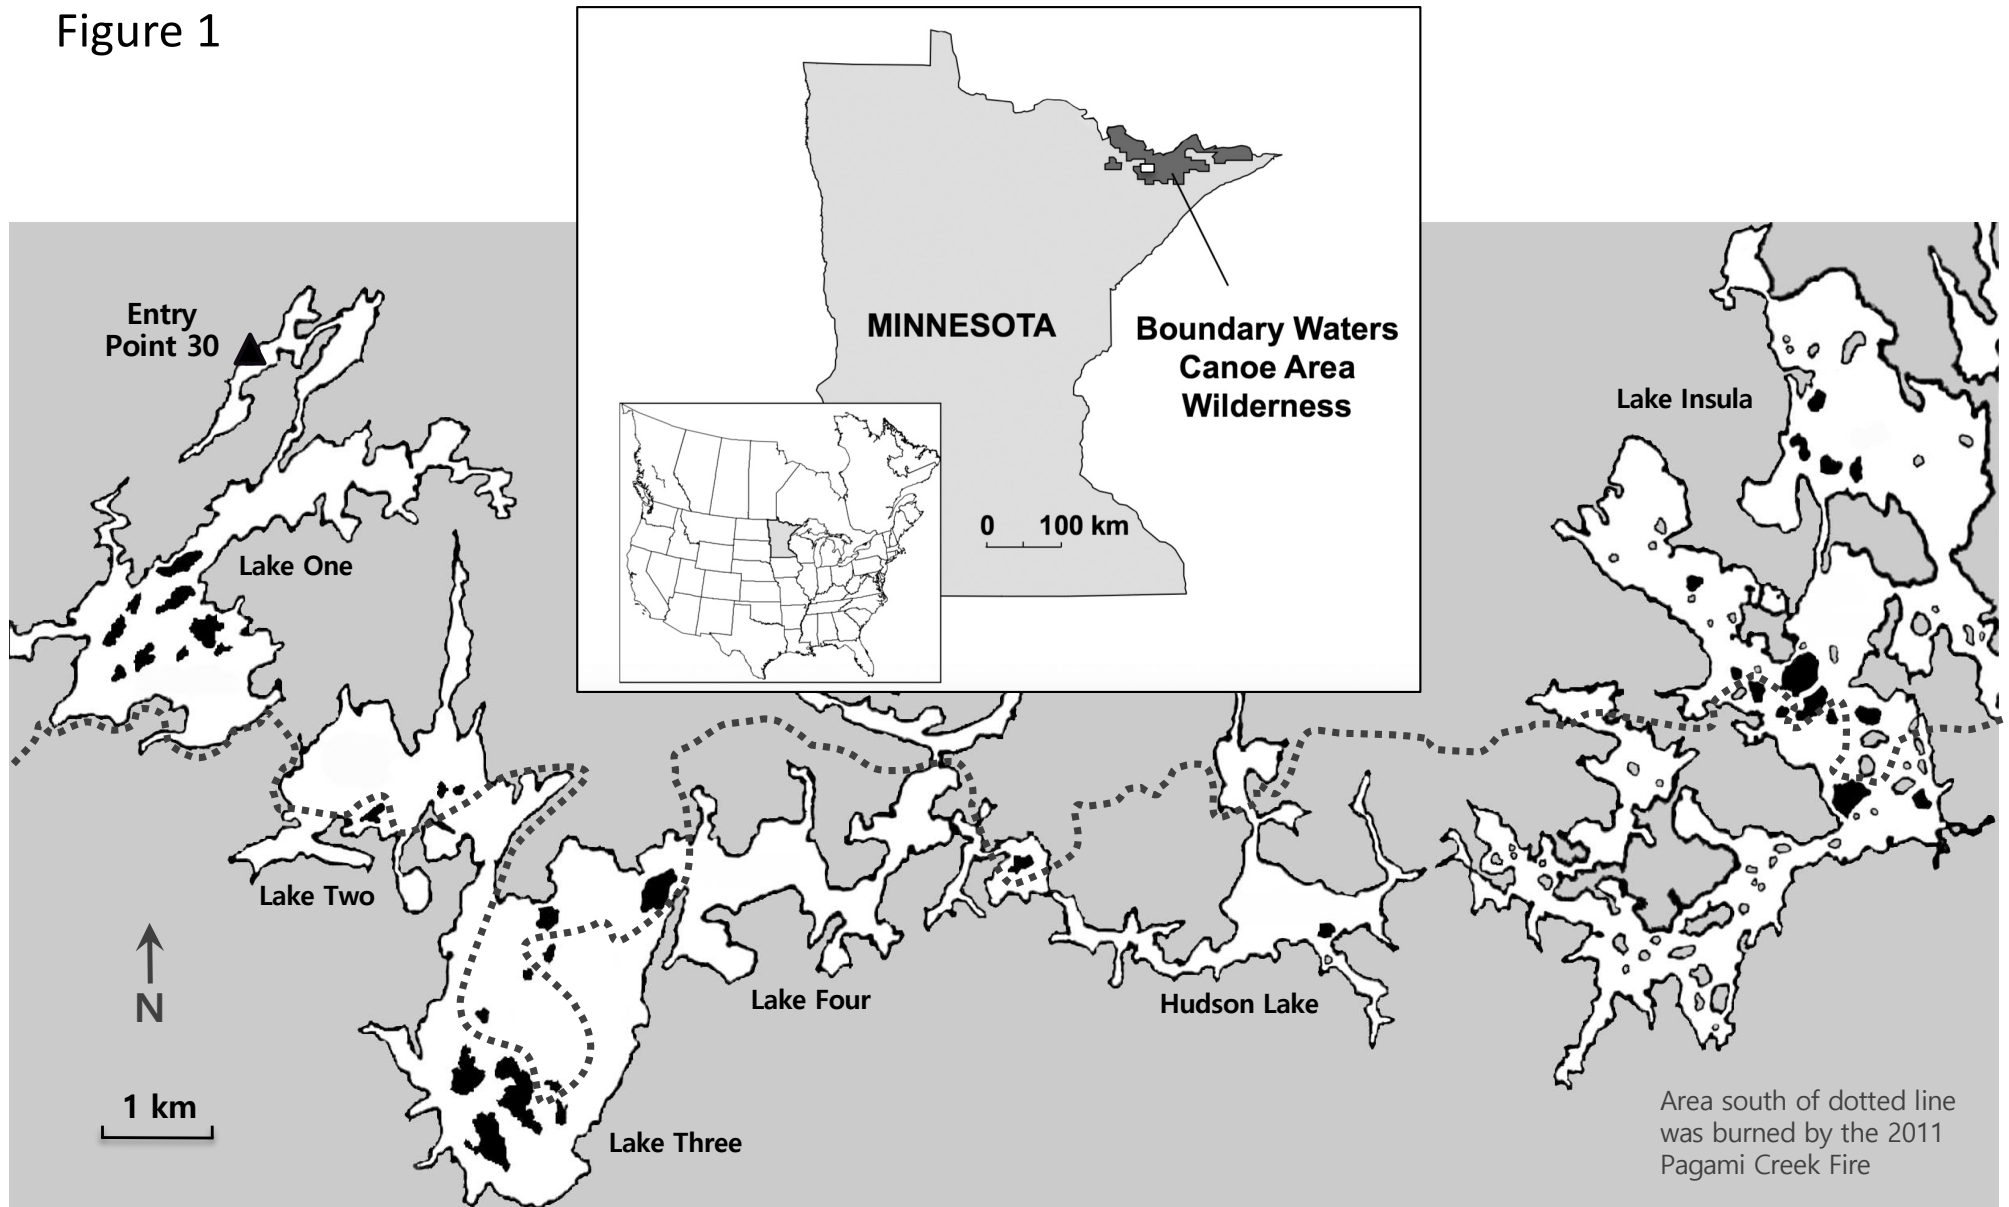

Figure 1. Map showing the location of the Boundary Waters Canoe Area Wilderness in northern Minnesota (inset) and the study area (small white rectangle), which has been enlarged to show the six connecting lakes (One, Two, Three, Four, Hudson and Insula) and the 38 islands that were sampled (shown in black). The dotted line represents the northern extent of the 2011 Pagami Creek Fire; the area south of the line was burned by the fire.

Figure 2 (on next page)

Metamodel depicting hypothesized relationships.

Solid lines show positive relationships; dashed lines show negative relationships.

Figure 2

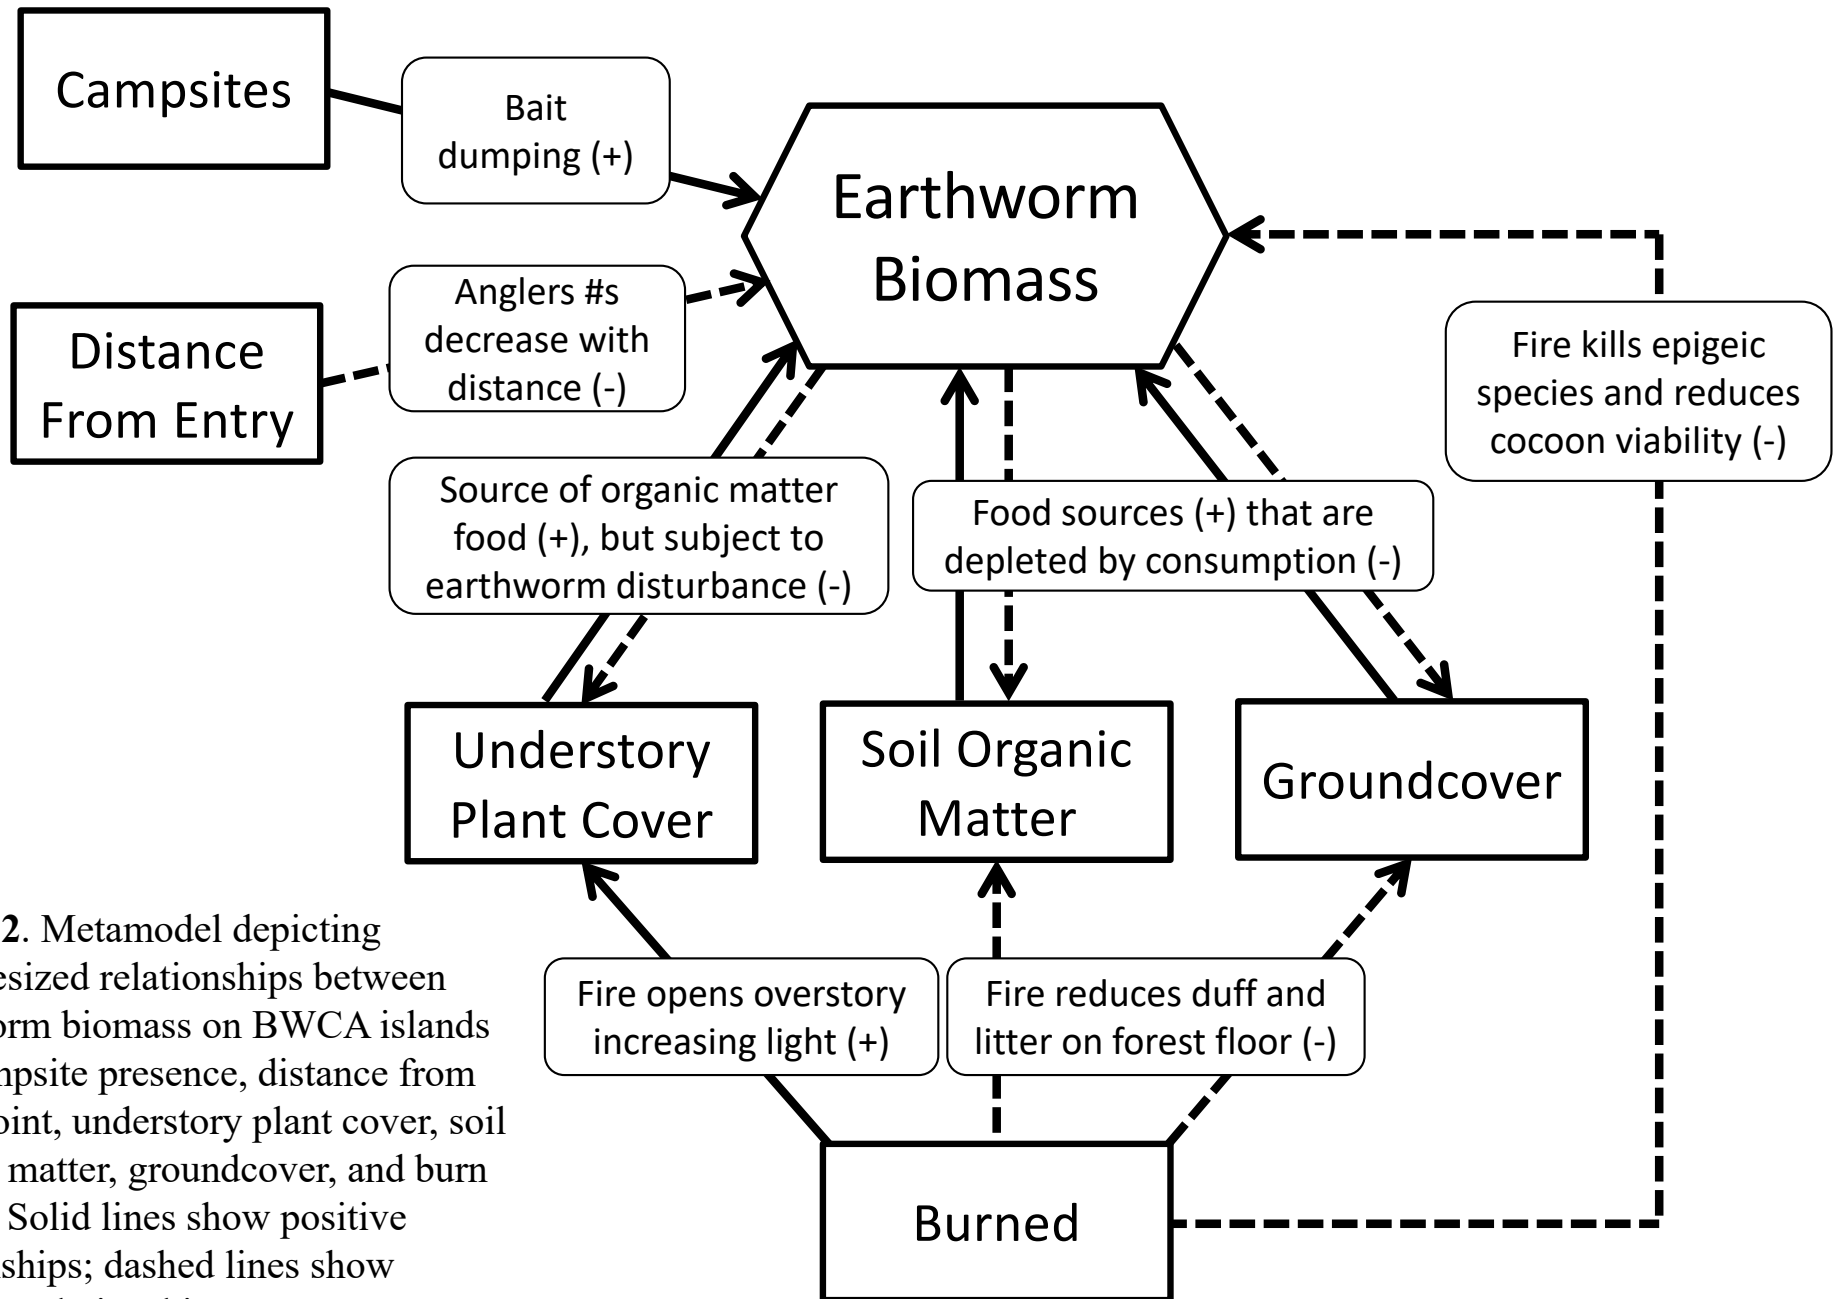

Figure 2. Metamodel depicting hypothesized relationships between earthworm biomass on BWCA islands and campsite presence, distance from entry point, understory plant cover, soil organic matter, groundcover, and burn history. Solid lines show positive relationships; dashed lines show negative relationships.

Figure 3(on next page)

Interactive effects influencing earthworm biomass.

The effect of campsite presence and fire history on earthworm biomass and density. Values are mean (± 1 SEM). GLM analyses indicated a significant campsite*burn interaction for earthworm density (A), but not earthworm biomass (B).

Figure 3

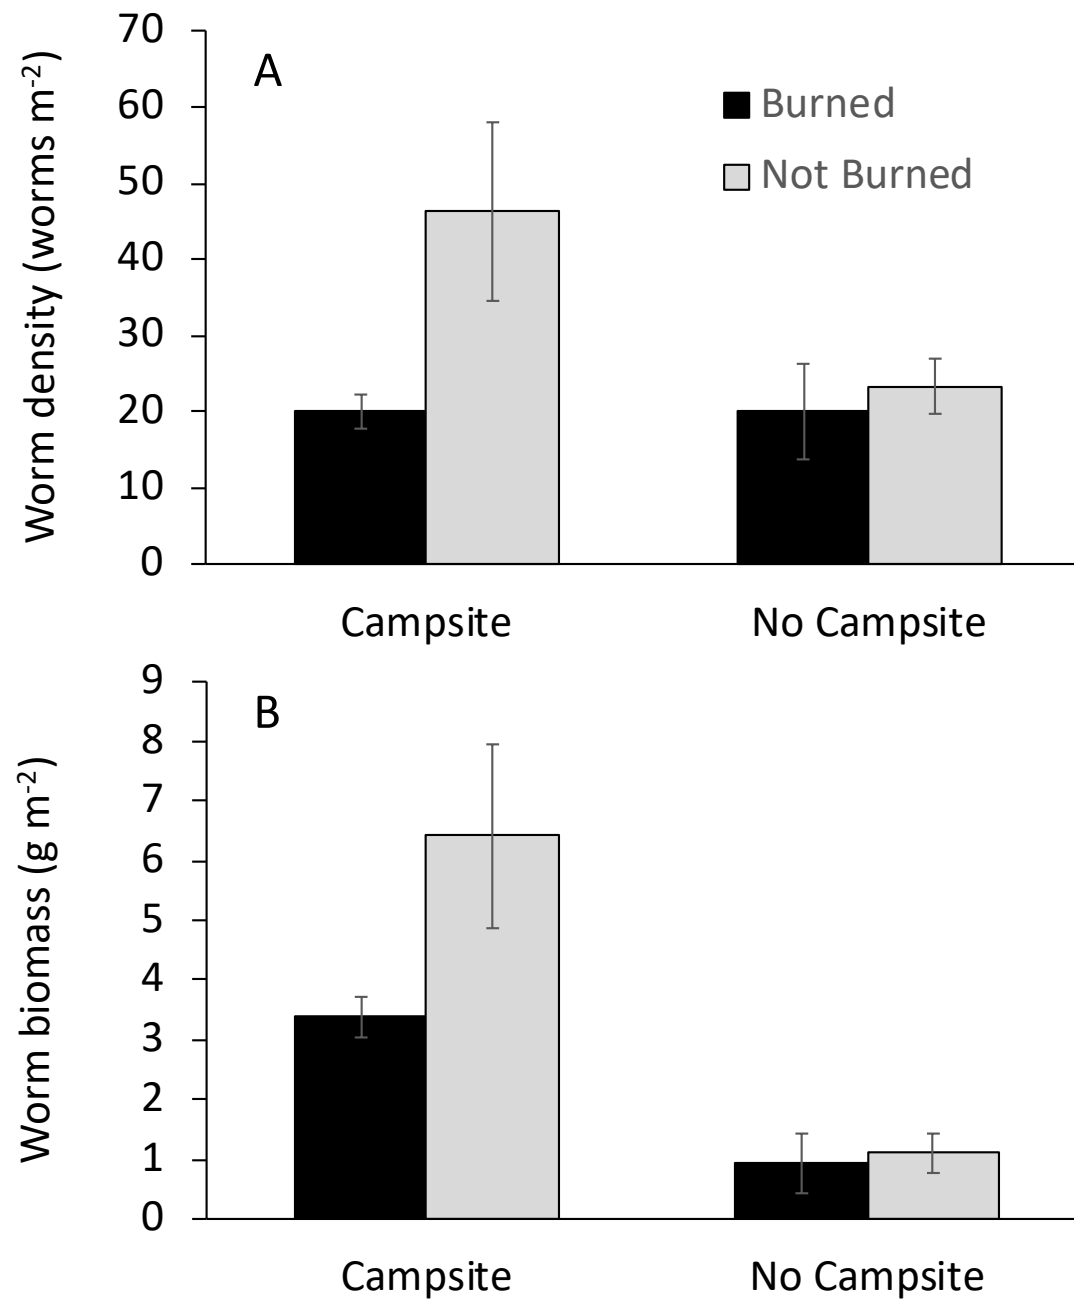

Figure 4 (on next page)

Interactive effects influencing earthworm biomass.

The interaction between entry point distance and burn history (A), and entry point distance and campsite presence (B) on earthworm biomass.

Figure 4

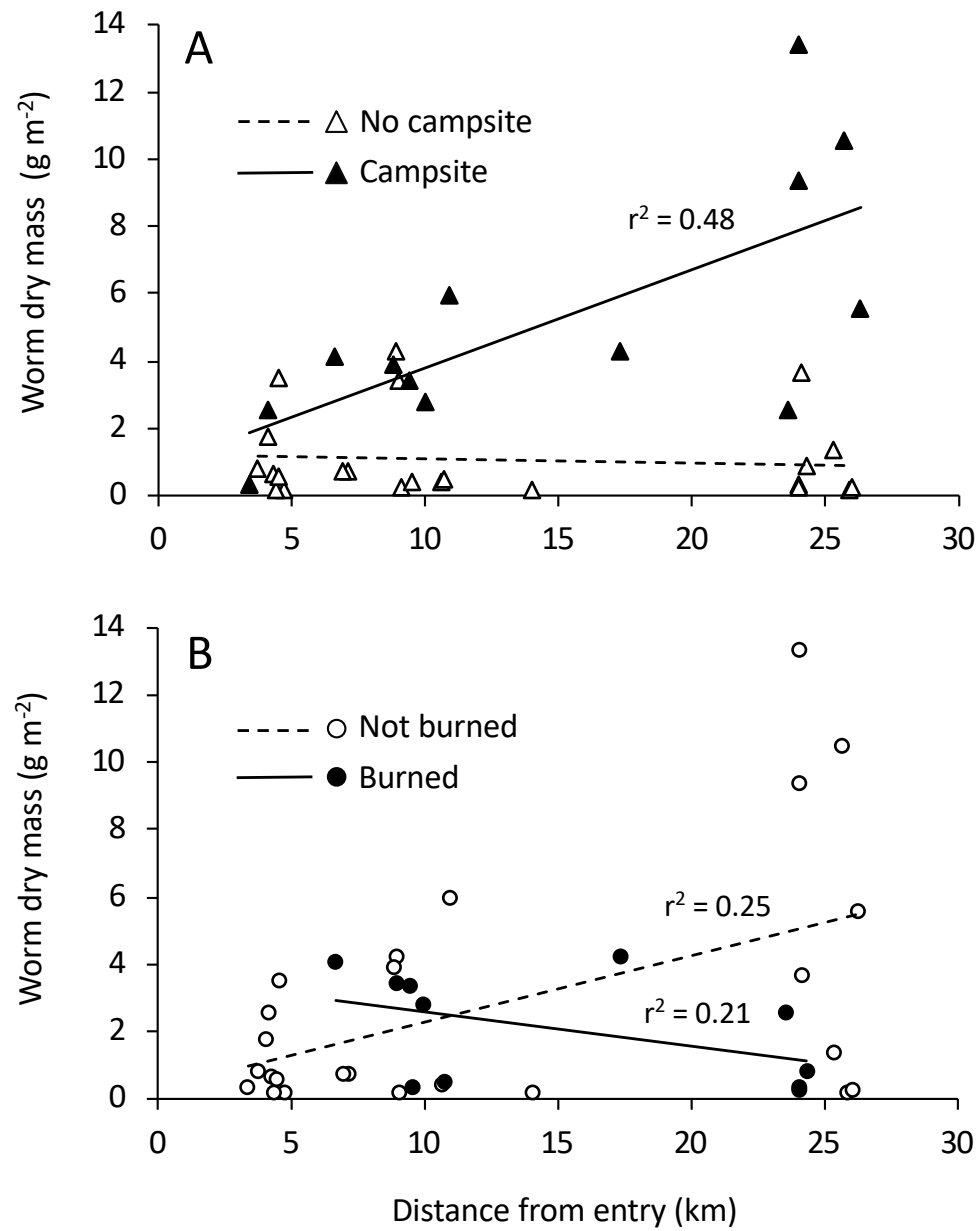

Figure 5(on next page)

Structural equation model representing the relationships between study variables and earthworm biomass.

Latent variables associated with endogenous factors are not shown. Solid arrows indicate positive effects; dashed arrows indicate negative effects. Dotted grey arrows labeled “ns” indicated non-significant relationships ($P > 0.10$). Model parameters are as follows: chi-square = 6.32, $df = 9$, $p = 0.71$; GFI = 0.96; RMSEA = 0.00; SRMR = 0.081.
