Plant resistance against insect herbivory has greatly focused on antibiosis, whereby the plant has a deleterious effect on the herbivore, and antixenosis, whereby the plant is able to direct the herbivore away from it. Although these two types of resistance may reduce injury and yield loss, they can produce selection pressures on insect herbivores that lead to resistance. Tolerance, on the other hand, is a more sustainable pest management strategy because it involves only a plant response and therefore does not cause evolution of resistance in target pest populations. Despite its attractive attributes, tolerance has been poorly studied and understood. In this critical, interpretive review, we discuss tolerance to insect herbivory and the biological and socioeconomic factors that have limited its use in plant resistance and integrated pest management. First, tolerance is difficult to identify, and the mechanisms conferring it are poorly understood. Second, the genetics of tolerance are mostly unknown. Third, several obstacles hinder the establishment of high-throughput phenotyping methods for large-scale screening of tolerance. Fourth, tolerance has received little attention from entomologists because, for most, their primary interest, research training, and funding opportunities are in mechanisms which affect pest biology, not plant biology. Fifth, the efforts of plant resistance are directed at controlling pest populations rather than managing plant stress. We conclude this paper by discussing future research and development activities.

**12 Abstract**

13 Plant resistance against insect herbivory has greatly focused on antibiosis, whereby the plant has  
14 a deleterious effect on the herbivore, and antixenosis, whereby the plant is able to direct the  
15 herbivore away from it. Although these two types of resistance may reduce injury and yield loss,  
16 they can produce selection pressures on insect herbivores that lead to resistance. Tolerance, on  
17 the other hand, is a more sustainable pest management strategy because it involves only a plant  
18 response and therefore does not cause evolution of resistance in target pest populations. Despite  
19 its attractive attributes, tolerance has been poorly studied and understood. In this critical,  
20 interpretive review, we discuss tolerance to insect herbivory and the biological and  
21 socioeconomic factors that have limited its use in plant resistance and integrated pest  
22 management. First, tolerance is difficult to identify, and the mechanisms conferring it are poorly  
23 understood. Second, the genetics of tolerance are mostly unknown. Third, several obstacles  
24 hinder the establishment of high-throughput phenotyping methods for large-scale screening of  
25 tolerance. Fourth, tolerance has received little attention from entomologists because, for most,  
26 their primary interest, research training, and funding opportunities are in mechanisms which  
27 affect pest biology, not plant biology. Fifth, the efforts of plant resistance are directed at  
28 controlling pest populations rather than managing plant stress. We conclude this paper by  
29 discussing future research and development activities.

## 32 INTRODUCTION

33           Is tolerance the forgotten child of plant resistance? Its attributes are so appealing, yet it  
34 has received the least attention of the three types of plant resistance. As an insect pest  
35 management tactic, tolerance may be the consummate strategy (Pedigo & Higley 1992). This is  
36 because a central tenet of integrated pest management (IPM) is that we tolerate some amount of  
37 pest injury. By making plants more tolerant of injury, we are achieving this important goal.  
38 Another goal is to use tactics that impose little selection pressure that will lead to pest resistance  
39 to those tactics. Contrary to antixenosis and antibiosis, tolerance does not affect insect biology or  
40 behavior (Smith 2005); therefore, pests cannot become resistant to tolerant plants. Clearly, the  
41 conceptual advantages of tolerance in plant resistance cannot be discounted.

42           We believe there are several reasons why tolerance has not been developed as  
43 successfully as antibiosis and antixenosis. First, tolerance is difficult to identify, and the  
44 mechanisms conferring it are poorly understood. Second, the genetics of tolerance are mostly  
45 unknown. Third, several obstacles still hinder the establishment of high-throughput phenotyping  
46 methods for large-scale screening of tolerance. Fourth, tolerance has received little attention  
47 from entomologists because, for most, their primary interest, research training, and funding  
48 opportunities are in mechanisms which affect pest biology, not plant biology. Fifth, the efforts of  
49 plant resistance are still directed at controlling pest populations rather than managing plant stress.  
50 In this paper, we discuss tolerance and the factors that have limited its use in plant resistance and  
51 IPM.

## 52 SURVEY METHODOLOGY

53           Primary and secondary literature relevant to the topic of this paper was assessed using  
54 Web of Science (Clarivate Analytics) and Google Scholar. Key words such as “plant tolerance,”

55 “host plant resistance,” “plant resistance,” “insect resistance,” “plant breeding,” “pest  
56 resistance,” “antibiosis,” and “antixenosis” were searched between 1 January and 31 May, 2017.

## 57 **DEFINITIONS AND CONCEPTS**

58 Before discussing the five factors above in detail, we first need to define tolerance. In this  
59 instance, precisely defining terms is important because there continues to be considerable  
60 overlap in plant resistance definitions. At the outset, we recognize tolerance as distinctly  
61 different from the two other resistance types: antibiosis and antixenosis.

62 Antibiosis is a type of resistance that contains at least one plant characteristic that affects  
63 pest biology in a deleterious manner. Antixenosis is a type of resistance that contains at least one  
64 plant characteristic that directs a pest away from it. Tolerance is a type of resistance that causes  
65 the plant to compensate for pest injury to a degree exceeding non-tolerant plants (Kogan &  
66 Ortman 1978; Painter 1951; Smith 2005). In an evolutionary context, tolerance is defined as the  
67 slope of the line describing the association between fitness and level of damage for a set of  
68 genetically related plants (Strauss & Agrawal 1999). In agronomic situations, tolerant crop  
69 varieties are able to withstand injury and produce acceptable yields (Flinn et al. 2001; Qiu et al.  
70 2011; Webster 1990; Webster et al. 1991). From an ecological perspective, tolerant plants can  
71 maintain fitness in response to pest injury (Núñez-Farfán et al. 2007; Rosenthal & Kotanen  
72 1994).

73 Both antibiosis and antixenosis involve a plant response and a pest response. However, in  
74 the case of tolerance only a plant response is involved. Therefore, there is a nonreciprocal  
75 process associated with tolerance (Smith 2005). This non-reciprocity has important ramifications  
76 when considering the use of tolerant cultivars in IPM programs.

77 Like antibiosis and antixenosis, tolerance is a type of resistance. Tolerance (as well as  
78 antibiosis and antixenosis) is not a mechanism of resistance (Smith 1997). There are numerous  
79 mechanisms conferring tolerance (Koch et al. 2016; Strauss & Agrawal 1999; Tiffin 2000), just  
80 as there are numerous mechanisms for antibiosis and antixenosis (Du et al. 2009; War et al.  
81 2012). Therefore, different and distinct mechanisms that enhance pest mortality collectively  
82 belong to the antibiosis resistance type.

83 What do we mean by stating that tolerant hosts can compensate for injury better than  
84 non-tolerant hosts? Plant response to biotic injury depends on four factors: the intensity of injury,  
85 the time of injury, the type of injury, the plant part injured, and interactions with environmental  
86 factors (Peterson & Higley 2001). The intensity of injury is very important when considering the  
87 potential impact of the stressor on host yield or fitness. The relationship was described in the  
88 form of a damage curve by Tammes (1961), and has since been supported by substantial  
89 empirical evidence (Shelton et al. 1990).

90 Pedigo et al. (1986) defined portions of the damage curve more than two decades after its  
91 inception (Fig. 1). The damage curve can be used to present some of the basic aspects of  
92 tolerance. Although the initial portion of the damage curve is termed the tolerant region, there  
93 are actually four portions that can theoretically be expressed differentially by tolerant plants  
94 when compared with nontolerant plants. The damage curve can be altered by extending the  
95 initial zero slope of the damage curve; i.e., no damage per unit injury is expressed at higher  
96 levels of injury for tolerant plants than for nontolerant plants (Fig. 2a). Tolerant plants also may  
97 be able to affect the compensation area of the damage curve in two ways. First, because this area  
98 is curvilinear (with a negative decreasing slope), tolerant plants may express less damage per  
99 unit injury (Fig. 2b). Second, the slope is not altered, but the curvilinear portion is extended into

100 higher levels of injury (Fig. 2c). The linear portion can also be affected by tolerant plants in two  
101 ways. First, the constant, negative slope (constant damage per unit injury) may have a less  
102 negative slope for tolerant plants (Fig. 2d). Second, the linear portion may be shorter. Therefore,  
103 desensitization and inherent impunity would occur at a higher yield (Fig. 2e). The last portion,  
104 overcompensation (increasing yield per unit injury), can be expressed by both tolerant plants and  
105 nontolerant plants; however, tolerant plants may express a higher yield increase per unit injury  
106 (Fig. 2f).

107 As we have shown, the damage curve theoretically can be altered by plants expressing  
108 tolerance. The challenge remains to identify empirically the portion or portions of the damage  
109 curve where tolerance is expressed by plants. In addition, simply because portions are identified  
110 where tolerance is expressed does not mean those would be practical targets for plant breeding.  
111 The tolerance, overcompensation, and compensation portions (Fig. 2a,b,f) most likely would be  
112 the most practical, producer accepted, and economic targets for enhancing tolerance. Enhancing  
113 tolerance in the linearity, desensitization, and inherent impunity portions (Fig. 2c,d,e) most likely  
114 would not be acceptable to producers because economic yield loss would already be occurring in  
115 these portions, except perhaps for lower injury areas of the linearity portion.

116 Tolerance can also be expressed in the context of economic injury level (EIL) parameters.  
117 The relationship between damage per unit injury and the EIL typically takes the form of Fig. 3.  
118 Because a tolerant plant ultimately expresses less damage per unit injury, the EIL will be greater  
119 for most levels of injury. This relationship can also be expressed when considering pest  
120 population levels over time and the EIL (Fig. 3).

## 121 **CONSTRAINTS ON THE DEVELOPMENT AND USE OF TOLERANCE**

### 122 **Identifying tolerance and characterizing tolerance mechanisms is difficult**

123           A major factor contributing to the predominance of antibiosis and antixenosis is sheer  
124 amenability. Antibiosis mechanisms often have been relatively easy to identify and breed for,  
125 mainly because the effects on herbivorous arthropods are readily apparent. We realize that the  
126 precise biochemical mechanisms for antibiosis in many systems are not known. For example,  
127 larval survival of the wheat stem sawfly, *Cephus cinctus*, is reduced by quantitative trait loci  
128 (QTL) on wheat chromosomes 2A, 3A, and 5B (Varella et al. 2015). Although specific  
129 mechanisms causing larval mortality have yet to be determined, this constraint has not hindered  
130 the identification of antibiosis and the ability to breed for wheat resistance to this pest.

131           Although antixenosis mechanisms are not as readily identifiable as antibiosis  
132 mechanisms, they still are more apparent than tolerance mechanisms. This is because antixenotic  
133 mechanisms usually involve morphological features that can be visually identified. For example,  
134 the frego bract character in cotton and glandular trichomes in alfalfa (both of which discourage  
135 larval feeding and oviposition) are very apparent and efficacious (Jenkins & Parrott 1971;  
136 Ranger & Hower 2001). Even less visually apparent mechanisms such as surface waxes, tissue  
137 thickness, and chemical deterrents can be readily identified and assayed (Chamarthi et al. 2011;  
138 Jindal & Dhaliwal 2011; Weaver et al. 2009).

139           In contrast to antixenosis and antibiosis, relatively little is known about tolerance.  
140 Tolerance to arthropod injury has been identified in alfalfa, barley, rice, sorghum, maize, wheat,  
141 cotton, cowpea, okra, muskmelon, turnip, and tea (Velusamy & Heinrichs 1986), northern red  
142 oak, Spanish cedar, *Brassica rapa*, tall fescue, and perennial ryegrass (Strauss & Agrawal 1999),  
143 lentils, sugarcane, soybean, potato, switchgrass, and cacao (Koch et al. 2016), cassava, tomato,  
144 and strawberry (Byrne et al. 1982; Gilbert et al. 1966; Schuster et al. 1980). In some of these  
145 commodities, tolerance is a very important resistance attribute. For example, the resistance of

146 sorghum to greenbug, *Schizaphis graminum*, is dependent on the survival of seedlings in  
147 response to feeding injury. This is clearly a tolerance response because resistant cultivars have  
148 no effect on greenbug biology or behavior (Schuster & Starks 1973). In barley, the identification  
149 of Russian wheat aphid, *Diuraphis noxia*, populations virulent to resistance genes has recently  
150 prompted the development of tolerant cultivars (e.g. “Sydney” and “Stoneham”) in an attempt to  
151 reduce selection pressure on the aphid population, thus increasing the durability of genotypes  
152 (Haley et al. 2004; Marithus & Smith 2012; Mornhinweg et al. 2009; Mornhinweg et al. 2012).  
153 Despite its successful use in some crops, little is known about the mechanisms underlying  
154 tolerance.

155 Tolerance is currently believed to be caused by six general physiological mechanisms: (i)  
156 increased net photosynthetic rate after herbivory, (ii) high relative growth rates, (iii) increased  
157 branching or tillering, (iv) pre-existing high levels of carbon storage in roots, (v) increased  
158 resource allocation from root to shoot after damage (Strauss & Agrawal 1999), and (vi) up-  
159 regulation of detoxification mechanisms to counteract deleterious effects of herbivory (Koch et  
160 al. 2016). Possible morphological features of tolerance include protected meristems, number of  
161 meristems, and developmental plasticity (Rosenthal & Kotanen 1994). At the molecular level,  
162 only a few transcripts (e.g. SNF1-related kinases, peroxidases, and catalases) have been  
163 identified as been involved in tolerance to herbivory through resource allocation (Schwachtje et  
164 al. 2006) or reactive oxygen species (ROS) detoxification mechanisms (Ramm et al. 2013; Smith  
165 et al. 2010).

166 It is important to note that mechanisms that contribute to tolerance may vary with  
167 herbivore specialization (e.g. specialists, generalists) (Foyer et al. 2015), feeding guild (e.g.  
168 chewing, sucking) (Zhou et al. 2015), the plant’s symbiotic relationships (e.g. several milkweed

169 species show increased tolerance to herbivory when associated with arbuscular mycorrhizal  
170 fungi) (Tao et al. 2016) and environmental conditions (Wise & Abrahamson 2007). All of these  
171 factors complicate the identification and characterization of tolerance mechanisms. Also, some  
172 mechanisms are constitutively expressed while others are induced. Evaluation of germplasm  
173 showing induced tolerance must be done in the presence of pest populations, which is often more  
174 challenging due to seasonal variation in pest infestation at any given location.

175       Many crop varieties expressing tolerance have been discovered fortuitously.  
176 Development of resistant cultivars usually has been the result of general screening for any  
177 expression of resistance. For example, the development of the alfalfa cultivar "Team," which is  
178 tolerant to alfalfa weevil, *Hypera postica*, injury, was the result of large-scale screenings of  
179 germplasm, in which more than two million seedlings were exposed to weevil infestation in an  
180 attempt to identify any resistance. After 10 years of breeding, "Team" was released in 1970. The  
181 cultivar is believed to express all three resistance types, but tolerance seems to be the dominant  
182 resistance factor (Barnes et al. 1970). It should be noted that the goal of the researchers was not  
183 to characterize mechanisms, but rather to produce a resistant variety. Large scale screenings  
184 focusing exclusively on plant tolerance have also been successful (Dunn et al. 2011).

### 185 **The genetics of tolerance is poorly understood**

186       The ability to predict phenotypic characteristics based on plant genotype is key to  
187 expedite the development of improved crops, mainly because it adds efficiency and precision to  
188 germplasm screening and selection. Nevertheless, understanding the genetics of plant tolerance  
189 to herbivory, as with any other trait, requires both the capability to detect polymorphic alleles  
190 and the recombination or segregation of these alleles.

191 To meet these requirements, large breeding populations need to be developed and  
192 screened. Lack of knowledge of the mechanisms underlying tolerance hinders the ability to  
193 precisely phenotype plants and interferes with the capacity of detecting polymorphisms. Despite  
194 the challenges, genetic variation in tolerance to herbivory has been demonstrated in crop and  
195 non-crop species (Marithus & Smith 2012; Punnuri et al. 2013; Shen & Bach 1997). Similar to  
196 antibiosis and antixenosis, tolerance seems to be mostly controlled by multiple loci and their  
197 interactions. Though QTL associated with tolerance to herbivory have been identified, to our  
198 knowledge, no gene has been cloned. Thus, further research should aim to enhance the genetic  
199 resolution of target QTL, which ultimately may result in the identification and cloning of causal  
200 genes.

201 **Establishing high-throughput screening methods for large-scale phenotyping of tolerance is**  
202 **difficult**

203 One of the bottlenecks of breeding for insect tolerance is the difficulty in identifying  
204 diagnostic traits that can be easily, precisely, and consistently quantified under natural and/or  
205 imposed insect pressure. Screening methods that are laborious or time-consuming might be  
206 adequate for research purposes, but are for the most part not useful for screening the large  
207 number of lines regularly phenotyped in plant breeding programs.

208 For example, wheat tolerance to the bird cherry-oat aphid, *Rhopalosiphum padi*, can be  
209 assessed using a diverse set of methods that target a variety of plant traits (e.g. grain yield,  
210 thousand kernel mass, biomass ratios, and development of roots and shoots) (Dunn et al. 2011;  
211 Lamb & MacKay 1995; Papp & Mesterházy 1993). However, not all methods allow for the  
212 evaluation of thousands of plants in a timely manner (Dunn et al. 2011). Thus, the establishment  
213 of high-throughput phenotyping methods that allow for the precise characterization of a large

214 number of lines will greatly contribute for the development of tolerant crop plants. Challenges  
215 associated with implementing high-throughput phenotyping for plant breeding programs are  
216 associated with costs of equipment, facilities, and software licenses (required for data analysis),  
217 lack of personnel trained for manipulation of large data sets, and lack of standards for  
218 experimental design and data analysis (Goggin et al. 2015).

### 219 **Entomologists lack substantial training in plant biology**

220 Because entomologists have been the primary participants in research on plant resistance  
221 to insects, entomocentric views have prevailed. Consequently, instead of concentrating on plant  
222 responses to insect-induced injury, entomologists have often used the plant to deliver a control  
223 tactic. This strategy reflects an inherent disadvantage in research training specialization  
224 (overspecialization?) of contemporary scientists (Jacobs & Frickel 2009; Rhoten 2004; Welter  
225 1989). Very few entomologists have had formal training in aspects of plant biology, such as  
226 photosynthesis, metabolism, anatomy, and water relations. Entomologists trained to consider the  
227 plant in insect-plant interactions potentially would improve research and development of tolerant  
228 cultivars. Additionally, interdisciplinary research teams may be able to develop tolerant cultivars.  
229 However, interdisciplinary research incorporating aspects of pest biology, plant physiology, and  
230 agronomy is still in its infancy (Peterson 2001; Peterson & Higley 2001).

### 231 **Plant resistance efforts are targeted toward the control of pest populations**

232 We believe that plant resistance research, although overtly very progressive and fitting in  
233 well with IPM, has largely followed a unilateral approach to pest management, similar to the  
234 control tactic of insecticide use common in the 1950s and early 1960s. Through antixenosis, and  
235 especially antibiosis mechanisms, resistant cultivars essentially are controlling insect  
236 populations. Unlike insecticide use, the adverse environmental impacts of using resistant

237 cultivars are quite low. In this respect, resistant cultivars satisfy one objective of IPM:  
238 minimizing detrimental environmental effects. However, cultivars with antibiotic mechanisms  
239 place selection pressure on insect populations, potentially encouraging the development of  
240 resistance. Although, resistant cultivars may represent a more desirable control tactic, they do not  
241 necessarily represent a truly sustainable pest management practice. New approaches for  
242 incorporating resistance in plants also will not be sustainable. For example, plants that are  
243 engineered to produce the *Bacillus thuringiensis* (Bt) toxin have selected for resistance (even  
244 when pest populations were not economic) (Tabashnik et al. 2008).

245         The issue of control versus management in IPM is a critical factor when attempting to  
246 understand why tolerance is not as prominent in plant resistance. The terms "control" and  
247 "management" as they relate to pest management have been discussed (Higley & Pedigo 1993;  
248 Higley & Pedigo 1996; Menalled et al. 2016; Pedigo & Higley 1996; Pedigo & Rice 2009).  
249 Briefly, "Control" implies a program focused on the pests themselves, and, in particular killing  
250 pests. Therefore, this often results in strong selection pressure for resistance. The focus on killing  
251 pests includes the highly efficacious antibiotic tactic represented by Bt crops. "Management"  
252 implies a program focused on the "judicious use of means to accomplish a desired end" (Pedigo  
253 & Higley 1996). Tolerance, then, as a type of plant resistance, clearly fits well with management.

#### 254 **Other biological factors**

255         Conceptually, tolerance has very attractive attributes for use in IPM programs. However,  
256 because tolerance has been so poorly studied and understood, we do not know if or how much  
257 specific interactions with the environment (such as drought or heat stress) will render the tolerant  
258 variety completely susceptible to pest injury. This is especially relevant in the face of climate  
259 change and the increase in drought-prone areas. In non-crop species for instance, drought has

260 been shown to limit a plant's ability to tolerate herbivory (Atala & Gianoli 2009; Gonzáles et al.  
261 2008). But even closely related species of plants may respond differently to herbivory under  
262 drought conditions (Shibel & Heard 2016). Thus, the impact of environment on the plant's  
263 ability to tolerate insect herbivory might have to be assessed for each crop species and/or variety.

264 In several crop systems, some arthropod species move from one crop species to another  
265 during their life cycle. For example, in North Carolina the corn earworm, *Helicoverpa zea*, may  
266 injure corn, tobacco, wild hosts, soybean, and cotton. Having just one crop species in an area  
267 tolerant to corn earworm injury may result in unacceptable populations for the other crop  
268 species.

#### 269 **Socioeconomic factors**

270 In the U.S., growers attempt to control pests to avoid risk as much as, if not more, than to  
271 optimize yields (Higley 2006). Understandably, then, growers may be uncomfortable with a  
272 large number of pests feeding on their tolerant cultivar. In this case, the cultivar may be able to  
273 tolerate the injury, but the grower cannot. The attitude that the "only good bug is a dead bug" is  
274 undoubtedly alive and well in modern farming systems. Additionally, private companies may not  
275 embrace tolerant cultivars because they do not want their customers to doubt that their varieties  
276 are indeed resistant. Therefore, education about tolerance and tolerant cultivars must be a priority  
277 if this resistance strategy is to be successful.

278 Tolerant cultivars must be agronomically desirable. Nguessen and Quisenberry (1994)  
279 identified several rice lines that are tolerant to rice weevil, *Sitophilus oryzae*, injury. However,  
280 they were not agronomically desirable. This is a major limitation to incorporating tolerance into  
281 crops and must be addressed by researchers. Another major limitation is that tolerant crops may  
282 be more vulnerable to cosmetic damage than crops displaying other types of resistance.

283 Consumer preference for fruits and vegetables, for example, is influenced by product  
284 appearance. Thus consumer preference for undamaged food products might limit the use of  
285 tolerance in some crop species.

## 286 **CONCLUSIONS AND RECOMMENDATIONS**

287         Although antixenosis and antibiosis may lessen or negate the need for pesticides applied  
288 to the crop, they can produce selective pressures on insect populations that are similar to  
289 pesticides. The management tactic may be more environmentally acceptable and therefore may  
290 be more popular with policy makers and the public, but if sufficient selective pressure is placed  
291 on the pest population the tactic is not sustainable in the long term (Kennedy et al. 1987; Tolmay  
292 et al. 2007). Tolerance, as a resistance mechanism, is very appealing because it is a sustainable  
293 tactic (Kennedy et al. 1987; Pedigo 1995; Pedigo & Rice 2009; Rausher 2001). By not placing  
294 selective pressure on insect populations, it essentially factors the pest out of the equation.  
295 Additionally, EILs for tolerant varieties would be substantially higher than for susceptible  
296 varieties. Therefore, reduced pesticide inputs would result. Because of these factors, tolerance is  
297 a more stabilizing management strategy for pests.

298         Velusamy and Heinrichs (1986) list three factors they believe are responsible for the lack  
299 of attention to tolerance. They include: a lack of suitable techniques to identify and incorporate  
300 tolerance into crops; the ability of tolerant cultivars to serve as reservoirs for insect vectors of  
301 viruses; and, the lack of basic information on the inheritance of tolerance. We believe they have  
302 identified three factors that potentially constrain the development of tolerance. However, we  
303 believe our factors are more encompassing, reflecting the biological, economic, and social  
304 constraints on tolerance development. For example, the lack of suitable techniques to identify

305 tolerance is really a reflection of the lack of understanding about basic physiological mechanisms  
306 underlying tolerance.

307         Before substantial work on tolerance development can occur, we must conduct basic  
308 research on the physiological and biochemical mechanisms of tolerance. This must involve  
309 interdisciplinary research between plant scientists and entomologists. Beyond an  
310 interdisciplinary focus, it is important that there is awareness from applied researchers about  
311 research and findings from fundamental researchers and vice-versa. There are longstanding  
312 issues of lack of communication between ecologists and agricultural scientists (Higley et al.  
313 1993) and this must be addressed before tolerance can be appreciably advanced.

314         More generally, research on the physiological responses of plants to arthropod injury  
315 (irrespective of tolerance) must progress beyond what is currently known. Higley et al. (1993)  
316 argued that a focus on plant physiology provides a common language for characterizing plant  
317 stress and is essential for integrating understanding of stress. Peterson and Higley (1993) and  
318 Peterson (2001) discuss approaches for synthesizing plant responses to arthropod injury.

319         Based on the factors we have discussed above, we believe the development and use of  
320 tolerance in plant resistance to arthropods can be hastened by achieving the following goals: (1)  
321 research characterizing the physiological mechanisms underlying tolerance; (2) research  
322 determining the physiological responses of plants to arthropod injury; (3) encouragement of  
323 interdisciplinary research and communication among entomologists, plant scientists, ecologists,  
324 and molecular biologists; and, (4) progression of IPM theory to a true paradigm for managing  
325 plant stress. Ultimately, to understand the conceptual importance of tolerance to plant resistance,  
326 the importance of tolerance to IPM must be appreciated.

# Figure 1

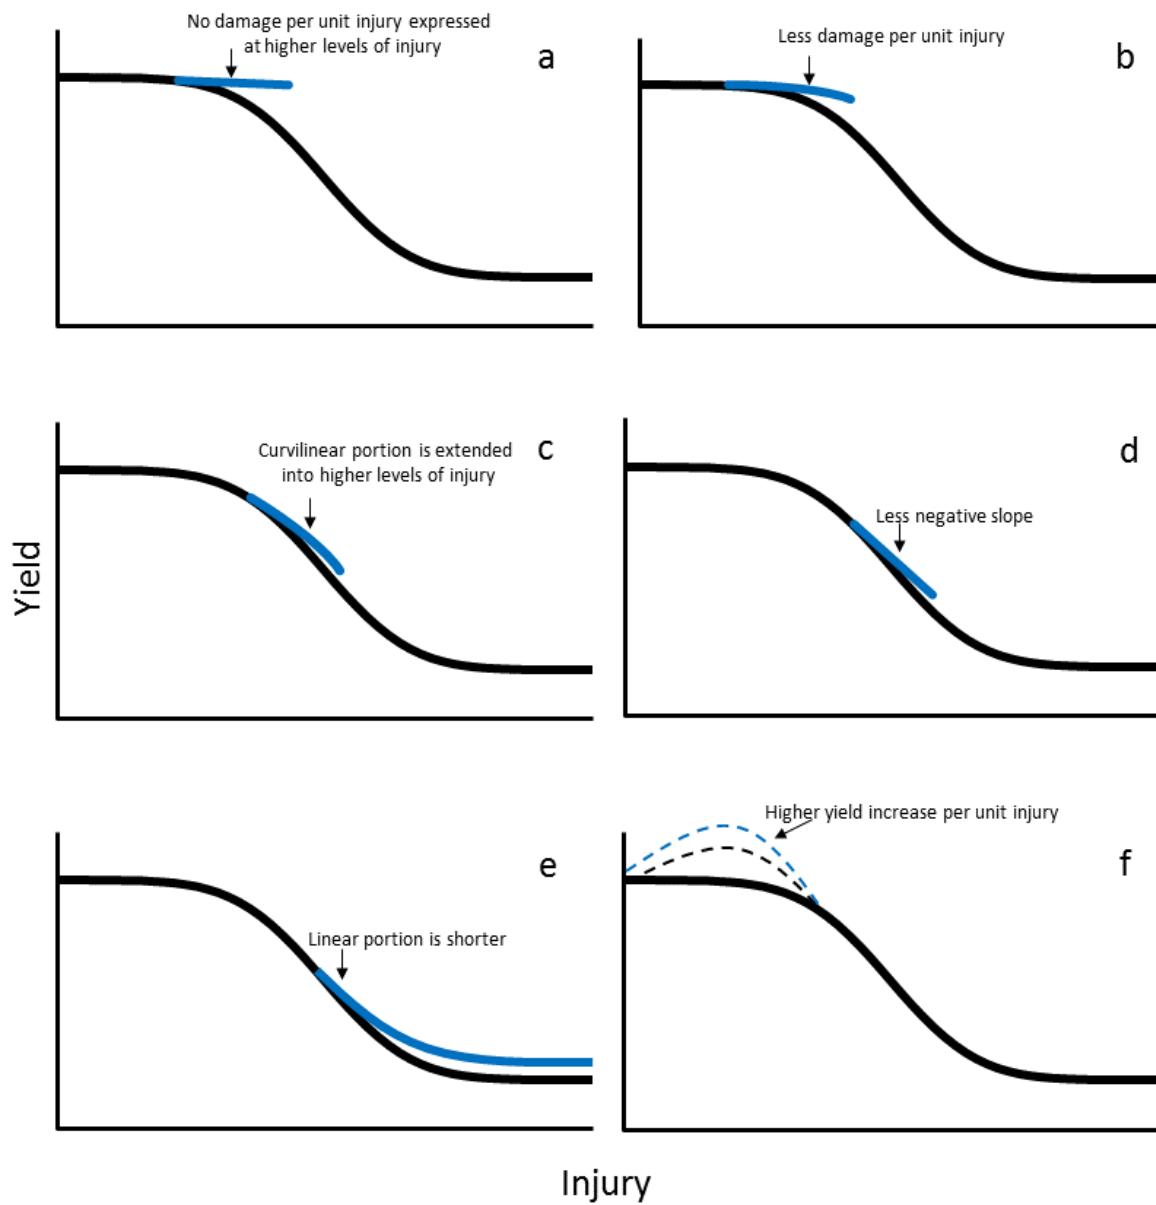

The damage curve relating intensity of injury to yield.

## Figure 2

The damage curve showing different portions where tolerance can be expressed.

a) shows extending the initial zero slope of the damage curve, i.e., no damage per unit injury may be expressed at higher levels of injury for tolerant plants than for nontolerant plants; b) shows that because this area is curvilinear (with a negative decreasing slope), tolerant plants may express less damage per unit injury; c) shows that the curvilinear portion may be extended into higher levels of injury; d) shows that the constant, negative slope (constant damage per unit injury) may have a less negative slope for tolerant plants; e) shows that the linear portion may be shorter; e) shows that desensitization and inherent impunity may occur at a higher yield; f) shows that overcompensation (increasing yield per unit injury), may be expressed by both tolerant plants and nontolerant plants, but tolerant plants may express a higher yield increase per unit injury.

## Figure 3

The relationship between injury (often expressed as number of insects), time, and the economic injury level with and without tolerance.
