2. Abstract

Background. Here we report on a meta-analysis of the attentional blink (AB) research focussed on specific reading impairment, commonly referred to as developmental dyslexia. The AB effect relates to a limitation in the allocation of attention over time and examined in a dual-target rapid serial visual presentation paradigm. When the second target appears in close temporal proximity to the first target, the second target is reported less accurately.

Method. A Web of Science search with terms 'dyslexia attentional blink' returned 13 AB experiments (11 papers) conducted with developmental dyslexia (9 were included in this meta-analysis). The main pattern of performance was lower overall accuracy in groups of individuals with dyslexia relative to typically reading peers. That is, a between-group main effect. This meta-analysis examined the size of the between-group effect in relation to physical presentation characteristics, which differed between and within experiments.

Results. Four noteworthy variables were related to the between group effect-size; fixation duration (positive relationship, $R^2 = .89$, $p < .01$, $n = 6$), maximum temporal position of T2 (negative relationship, $R^2 = .46$, $p < .05$, $n = 9$), the difference between the minimum and maximum temporal position of T2 (negative relationship, $R^2 = .53$, $p < .05$, $n = 9$), and the stimulus onset asynchrony (negative relationship, $R^2 = .46$, $p < .05$, $n = 9$).

Discussion. These are discussed with respect to the preparation of task-set, temporal orienting, and speed of processing, recommending these as considerations for future research.

3. Introduction

Aside from a specific difficulty with the typical acquisition of reading, developmental dyslexia has been associated with a number of cognitive weaknesses. One of these weaknesses is the ability to rapidly deploy attention across time (e.g. Hari & Renvall 2001; Tallal 1976). Here we focus on a single paradigm used to assess the rapid allocation of visual attention across time: a dual-target Rapid Serial Visual Presentation (RSVP) paradigm. Performance in this paradigm has been described as an ‘Attentional Blink’ (AB) effect. The AB is an attentional phenomenon whereby the processing of the first target (T1) is considered to disrupt the processing of a second target (T2) when the two targets appear in close temporal proximity (i.e. within 500 ms; Broadbent & Broadbent 1987; Raymond, Shapiro & Arnell 1992). The standard AB pattern is illustrated by the solid line in Figure 3.1. The main point to note is that at short inter-target intervals (e.g. 200 to 300 ms) T2 accuracy is lower than at long (e.g. 500 to 700 ms) intervals.

Figure 3.1 Four patterns of attentional blink (AB) performance: second target performance, given that the first target was correctly reported, as a function of the inter-target interval. The solid line depicts a standard AB performance. The dashed lines depict atypical AB performance related to deeper (panel A), longer (B), and deeper and longer AB effects (C), as well as lower overall accuracy (D).

56 In a review of the AB literature on developmental dyslexia, McLean, Castles,
 57 Coltheart, and Stuart (2010) demonstrated that the most common difference between
 58 dyslexic and typically reading groups was a main effect; that is, overall, the
 59 performance of the dyslexic readers was lower than that of typical readers. Therefore,
 60 rather than a difficulty in rapidly deploying attention across time (or “sluggish
 61 attentional shifting”, see Hari & Renvall 2001), dyslexic readers had a general
 62 difficulty with the AB paradigm. To illustrate this point, four different patterns of AB
 63 performance are presented in Figure 3.1. Specific difficulties with the AB may relate
 64 to deeper, longer, or deeper and longer effects (illustrated in Figure 3.1, panels A to
 65 C). However, what is noted in the dyslexia literature is the fourth option, lower
 66 overall accuracy (see Figure 3.1, panel D), reflecting a general difficulty with the
 67 dual-target paradigm. The current paper reports on a meta-analysis of the AB and
 68 dyslexia literature to explore this general difficulty.

69 The AB is considered to reflect a temporal limitation of attention. Most generally it is
 70 thought that a finite set of resources is required to consolidate a short-term
 71 representation of a target item for conscious report. While these resources are
 72 performing the consolidation of T1, the representation of T2 may decay and will not
 73 be available for conscious report (for reviews see Dux & Marois 2009; Martens &
 74 Wyble 2010). If this consolidation lasts longer, short-term representations waiting to
 75 be processed may decay; in order to update these representations for consolidation,
 76 regressive eye-movements made during reading may increase. This pattern of eye-
 77 movements has been noted in developmental dyslexia (Schneps et al. 2013).
 78 However, of the thirteen experiments published in this area, only three identify AB
 79 performance consistent with the notion of longer consolidation (or more rapid
 80 memory decay). These three experiments (Hari, Valta & Uutela 1999; Laasonen et al.

2012; Lallier et al. 2010) report that the accuracy of T2 report in dyslexia reaches the same level of accuracy as that of typical readers at long inter-target intervals; however, the time required to reach this accuracy is longer for dyslexic than typical readers. The majority of the experiments do not demonstrate this interaction, with accuracy remaining lower in dyslexic readers across all inter-target intervals (Badcock, Hogben & Fletcher 2008; Buchholz & Aimola Davies 2007; Facchetti et al. 2008; Lallier, Donnadieu & Valdois 2010; McLean et al. 2010; Visser, Boden & Giaschi 2004). One anomalous experiment reports higher accuracy across all inter-target intervals in a group of dyslexic readers (Lacroix et al. 2005): this will be considered in the discussion. If the majority of the evidence points to a general deficit in the AB paradigm for dyslexic readers, what underpins the general deficit?

When McLean et al. (2010) added single-target RSVP accuracy as a covariate in their analyses, twenty per cent of the dual-target RSVP performance difference between dyslexic and typical readers was accounted for. When controlling for single-target accuracy, in combination with a continuous-performance measure (accounting for nine per cent of the between-group variation), the between-group effect was no longer significant. Simulating this sort of inattention factor produces patterns of data that mimic dyslexic group performance (Roach, Edwards & Hogben 2004; Stuart, McAnally & Castles 2001). A general factor common to single- and dual-target RSVP paradigms may account for the between group differences noted in the AB and also have much broader implications beyond RSVP paradigms.

In RSVP paradigms, the target serial position varies in time relative to the onset of the RSVP. Single-target RSVP performance has been shown to be sensitive to this temporal variation. In a series of experiments, Ariga and Yokosawa (2008)

105 demonstrated that single-target RSVP accuracy increased as a function of foreperiod:
106 that is, at longer intervals from the onset of the RSVP, accuracy was higher. There is a
107 body of literature on the effects of temporal orienting, particularly with respect to
108 reaction time (Niemi & Näätänen 1981; Nobre, Correa & Coull 2007), but temporal
109 predictability and cueing have also been demonstrated to increase accuracy in the AB
110 (predictability Badcock et al. 2013; cueing Martens & Johnson 2005). Recently, Tang,
111 Badcock, and Visser (2013) demonstrated that some of the increases in dual-target
112 RSVP performance that occur with accuracy are attributable to learning the temporal
113 locations of targets. Given that temporal orienting has a role in both single- and dual-
114 target RSVPs, it presents as a candidate explanation for differences between dyslexic
115 and typical readers in RSVP performance.

116 Another element common to single- and dual-target RSVP paradigms is the
117 engagement of 'task-set'. Monsell proposed the concept of task-set with respect to
118 task-switching paradigms (Monsell 1996; Rogers & Monsell 1995) whereby, even
119 during a simple paradigm when the task was well known to the participants, a
120 cognitive model of the task-requirements must be engaged to complete the task. In an
121 RSVP paradigm the cognitive model would include searching for letters while
122 ignoring numbers and reporting the identity of letters. Therefore, this concept is
123 similar to the proposal that endogenous control of a 'visual-filter' is set up at the
124 outset of the RSVP task (Di Lollo et al. 2005). Di Lollo et al. suggest that the AB is
125 caused by a 'temporal loss of control' of the visual filter (but see Dell'Acqua et al.
126 2009; and also Olivers et al. 2011). It may be that the engagement of task-set accounts
127 for some of the time-related increases in single-target accuracy noted previously (i.e.
128 Ariga & Yokosawa 2008). Nevertheless, it is an additional candidate for the
129 differences between dyslexic and typical readers noted in RSVP performance.

130 The current investigation aimed to explore the basis of the significantly lower dual-
131 target RSVP accuracy that has been reported in dyslexic versus typical reading
132 groups. Based on evidence that single-target RSVP performance can account for the
133 dual-target RSVP between-group difference, we examined variability in temporal and
134 task-set related features via a meta-analysis of the AB literature on developmental
135 dyslexia. Temporal variations as well as the task-set requirements were selected as
136 common to both single- and dual-target RSVP tasks.

137 4. Method

138 Experiment Selection

139 Searching the Web of Science with the terms 'dyslexia attentional blink' returns 26
140 entries (4th of March 2014). When exclusions were made based on the comparison of
141 dyslexic readers with respect to age-matched typical readers on a dual-target task
142 requiring the identification and/or detection of two targets, 11 papers were relevant,
143 two of which include two experiments (Buchholz & Aimola Davies 2007; Visser,
144 Boden & Giaschi 2004). Badcock et al. (2011) report a reanalysis of their 2008 data.
145 This was not included in the present meta-analysis because it is not an independent
146 experiment. We excluded a further three experiments from the meta-analysis: 1) that
147 of Lacroix et al. (2005), who report a group difference with a direction different to all
148 other findings in the area (i.e. the dyslexic group had better performance than
149 controls, this is discussed in section 7.1); 2) experiment 1 from Buchholz and Aimola
150 Davies (2007), due to an anomalous effect-size (greater than 5 standard deviations
151 from the mean of the included experiments: the condition/experiment in which the
152 targets and distractors were numbers was excluded); 3) and the case study reported by

153 Lallier, Donnadieu, Berger, and Valdois (2010), for which a between-group effect-
154 size could not be computed.

155 The final number of experiments included was 9 (Badcock, Hogben & Fletcher 2008;
156 Experiment 2, Buchholz & Aimola Davies 2007; Facoetti et al. 2008; Hari, Valta &
157 Uutela 1999; Laasonen et al. 2012; Lallier, Donnadieu & Valdois 2010; McLean et al.
158 2010; Experiments 1 and 2, Visser, Boden & Giaschi 2004).

159 As is any field, a bias for the publication of significant results may mean that this
160 meta-analysis overestimates the true between-group difference. The main objective of
161 this analysis is to examine variables related to this between-group difference.
162 Noteworthy relationships will need to be directly manipulated in dyslexia
163 investigations prior to theoretical incorporation. This meta-analysis takes a further
164 step than is typical, exploring the meta-analytic variable with respect to task-
165 parameters. Whilst not all of the regular PRISMA checklist (Moher et al. 2009) are
166 applicable, this can be found in the supplementary materials of this article.

167 4.1 Variable selection and calculation

168 Eighteen variables were selected in 6 categories: stimulus onset asynchrony, fixation
169 duration, identity, RSVP position, temporal position and variability, and between-
170 group effect-size.

171 4.1.1 Stimulus onset asynchrony (SOA)

172 SOA represents the time period between the onset of one stimulus and the next. This
173 was determined from the method sections of the respective papers.

174 4.1.2 Fixation duration

175 The presentation duration (in ms) of the RSVP fixation symbol varied between
176 experiments. In three experiments (Laasonen et al. 2012; Visser, Boden & Giaschi
177 2004), the fixation remained on screen until a key press. These experiments were
178 excluded on the basis that the presentation duration of the fixation could not be
179 determined. Therefore, 6 experiments involving fixation duration were included in the
180 analyses.

181 4.1.3 Identity

182 By 'identity' we refer to the number of possible identities of T1, T2, and distractors.
183 For example, if T2 is a letter of the alphabet (e.g. letter X), and T1 as well as the
184 distractors are any letter other than that used for T2, there is 1 possible identity for T2,
185 25 possible identities for T1, and 25 for the distractors. Note: T1 and the distractor
186 identities both have 25 possibilities because there are randomly selected on each trial
187 and the T1 identity for one trial will be the distractor identity on another trial. This
188 example is for illustrative purposes, many studies omit 'I', 'O', and 'Q' due to the
189 limited masking properties.

190 The Visser et al. (2004) and McLean et al. (2010) experiments included random-dot
191 distractors with different 'identities' for each presentation. The precise number of
192 identities is difficult to determine and would regardless be a clear outlier. Therefore
193 these studies were excluded, leaving 6 experiments in the analyses involving
194 distractor identity.

195 4.1.4 RSVP Positions

196 This refers to the number of possible positions within the RSVP of T1 and T2 relative
 197 to fixation, and the number of T2 positions relative to T1. For example, if T1 were
 198 presented at positions 6, 7, and 8 in the RSVP, the total number of positions would be
 199 3. The number of T2 positions is calculated from the minimum T1 position plus the
 200 minimum inter-target intervals (ITIs or lag) through to the maximum T1 position plus
 201 the maximum ITI. For the current example, if T2 was presented at 12 ITIs
 202 immediately following T1, the minimum RSVP position would be 7 ($6 + 1$) and the
 203 maximum RSVP position would be 20 ($8 + 12$). Therefore there would be 14 possible
 204 RSVP positions for T2 relative to fixation. The number of T2 positions relative to T1
 205 would simply be the number of ITIs: 12 in the current example.

206 In the case of Facoetti et al. (2008) where only two targets and accompanying masks
 207 were presented, possible RSVP positions corresponds to the number of temporal
 208 positions relative to fixation. It is worth noting that this 'skeletal' RSVP paradigm
 209 may produce more variable results at the electrophysiological level (see Craston,
 210 Wyble & Bowman 2006).

211 4.1.5 Temporal position and variability

212 Temporal position is defined as the presentation time (in ms) of T1 relative to fixation
 213 offset, T2 relative to fixation offset, and T2 relative to T1 onset. For example, if T1 is
 214 presented at in RSVP position 6, 7, and 8, and the stimulus onset asynchrony is 100
 215 ms, this would correspond to 600 (minimum), 700, and 800 (maximum) ms. If T2 is
 216 presented at positions 1 to 12 following T1, this would correspond to 700 (min T1 +
 217 min T2 = $600 + 100$) through to 2000 (max T1 + max T2 = $800 + 1200$). These

timings also include the period of time between fixation offset and the onset of the RSVP.

Temporal position variability was calculated by taking the difference between the minimum and maximum temporal positions. To follow the example, for T1, $800 - 600 = 200$ ms; for T2, $2000 - 700 = 1300$ ms. T2 temporal position variability relative to T1 was the difference between the minimum and maximum ITIs: $1200 - 100 = 1100$ ms.

4.1.6 Between-group effect-size

The between-group effect-size was calculated in standard deviation units, Cohen's *d*. In all but one case, Cohen's *d* was derived from the ANOVA between-group effect statistics (*F* and degrees of freedom see <http://www.lyonsmorris.com/ma1/index.cfm>), depending on the availability of data in the published reports. Where the required data were not reported (i.e. Hari, Valta & Uutela 1999), an overall Cohen's *d* was based upon the between-group differences, averaged across all inter-target intervals, determined using Data Thief (<http://www.datathief.org/>).

This method of Cohen's *d* calculation does not allow for an estimate of variance therefore we have not included a Forest plot as part of this meta-analysis. All data points for each study are included in the Supplementary Materials.

4.2 Not correcting for multiple comparisons

Pearson's product-moment or Spearman's *rho* (non-parametric comparisons) correlation were calculated to examine the relationships between the dependent measures in this paper. Most critical are 17 correlations examining whether the between-group effect-size is related to any of the other factors. There has been no

241 correction for multiple comparisons in this instance. This decision has been made to
242 reduce the risk of Type 2 errors and on the basis that relationships of note in the meta-
243 analysis will need to be demonstrated empirically before they should be applied
244 theoretically (see Cabin & Mitchell 2000, for a discussion on considering correcting
245 for multiple comparisons).

246 5. Results

247 Descriptive statistics for the 18 parameters are presented in Table 5.1 (see
248 Supplementary Materials for all data points from each experiment). Of importance are
249 the normality tests: the SOA, T1 and T2 identity, number of T2 positions relative to
250 T1, and the minimum temporal position of T2 relative to T1 parameters, were not
251 normally distributed. Therefore, the relationship between each variable and effect-size
252 (Cohen's d) was assessed using Spearman non-parametric correlations, as opposed to
253 Pearson product-moment tests.

254 The correlation coefficients between the 18 parameters are presented in Table 5.2.
255 Most critical is the bottom row in which correlations for the relationship of between-
256 group effect-size to all other parameters are reported. There are four relationships
257 worth drawing attention to. The first is between Fixation Duration and effect-size ($r =$
258 $.95$, $p < 0.01$), indicating that the longer the fixation symbol is on the screen, the
259 greater the between-group difference. The second two are the negative correlations
260 between T2 max time and effect-size ($r = -.68$, $p < 0.05$) and T2 temporal variability
261 within the RSVP and effect-size ($r = -.73$, $p < 0.05$). These relationships indicate that
262 the greater the temporal variability of T1 and T2 within the RSVP, the smaller the
263 between-group difference. It is important to note that these variables are highly
264 correlated themselves ($r = .99$, $p < 0.01$). The fourth relationship of note is between

SOA and effect-size ($r = -.68$, $p > 0.05$). These are also negatively correlated indicating that the longer the SOA, the smaller the between-group difference. This relationship fails to reach significance but carries a large effect-size, and has a significant linear fit (see below) and has therefore been included. These relationships are presented in scatter plots, fitted with linear regression lines, in Figure 5.1; Fixation Duration, $R^2 = .89$, $p < .01$; T2 time max, $R^2 = .46$, $p < .05$; T2 time difference, $R^2 = .53$, $p < .05$; Stimulus Onset Asynchrony, $R^2 = .46$, $p < .05$.

282

283 Figure 5.1 Scatter plots and linear regression fitted curves for the relationship between the between-group effect-size (Cohen's d, y-axis) and,

284 from left, Fixation Duration (panel A; $R^2 = .89$, $p < .01$), T2 time max (B; $R^2 = .46$, $p < .05$), T2 time difference (C; $R^2 = .53$, $p < .05$), and285 Stimulus Onset Asynchrony (D; $R^2 = .46$, $p < .05$).

286 Please note, although the relationship between distracter identity and effect-size was
 287 large ($r = -.78$, $p = .07$), it was non-significant as was the linear fit ($R^2 = .61$, $p = .07$);
 288 therefore this was not flagged as part of the major discussion as the other four
 289 variables. In conjunction with this, distractor identity is heavily confounded with the
 290 maximum temporal position and temporal variability of the second target ($r = .93$ and
 291 $r = .92$, both $p < .01$). This is the case for a number of the variables and is mentioned
 292 in section 7.2.

293 6. Discussion

294 In a meta-analysis of attentional blink (AB) experiments focussed on developmental
 295 dyslexia, we examined whether the between-group effect-size was related to the
 296 variability of a series of presentation-related parameters. As noted by McLean et al.
 297 (2010), the clearest pattern in this literature is that performance of groups of
 298 individuals with dyslexia is poorer overall (see Figure 3.1 panel D); that is,
 299 statistically, there is a main effect, indicative of a general difficulty with the dual-
 300 target rapid serial visual presentation (RSVP) paradigm in dyslexia, rather than a
 301 specific AB effect. The results of the meta-analysis indicate four presentation-related
 302 variables were related to the between-group effect-size: fixation duration, maximum
 303 temporal position of T2 in the RSVP, variability of T2 temporal position in the RSVP,
 304 and the stimulus onset asynchrony (SOA). These have important implications for
 305 applications of the AB in specific populations and visual temporal attention in
 306 developmental dyslexia.

307 6.1 Fixation Duration

308 The longer the exposure duration of the fixation symbol, the greater the difference
 309 between-groups ($r = .95$, $p < 0.01$). To be clear (as mentioned), three of the nine AB

310 and dyslexia experiments included in the meta-analysis were excluded from the
311 analysis of fixation duration because the fixation symbol remained onscreen until a
312 key was pressed. Therefore, the finding is limited as it is based on six experiments,
313 with fixation durations of 0, 500, and 800 ms. Nevertheless, given the strength of the
314 relationship, it is worth further consideration¹.

315 The clearest explanation for a greater effect-size with longer fixation durations is
316 group differences in cognitive preparation during fixation presentation. If dyslexia
317 were associated with poor preparation, typical readers would be advantaged by
318 greater preparation before the offset of the fixation symbol. Therefore, with no
319 fixation symbol, typical readers would have a limited advantage due to preparation,
320 and the difference between the groups would be small. Such a scenario would account
321 for the data we observe here (see Figure 5.1). This could occur due to limited or slow
322 preparation. But preparation of what?

323 One possibility with respect to preparation is *task-set*. Task-set is a cognitive model of
324 the task requirements (Monsell 1996; Rogers & Monsell 1995). This is a similar
325 concept to the visual filter which is implicated in selection theories of the AB (e.g. Di
326 Lollo et al. 2005). For a task including two number targets in a series of black letter
327 distractors, the task-set would involve ignoring letters and attending to two numbers.
328 The task-set may also be influenced by goals. Ferlazzo et al. demonstrated that the
329 AB could be mediated by varying the instructions to participants (Ferlazzo et al.
330 2007). With standard instructions, e.g., report the identity of two numbers, an AB
331 effect was observed. However, with modified instructions consisting of a single goal,

¹ Please note, we have conducted two pilot studies with adults, unselected for reading ability, in which we manipulated fixation duration and find that this influences overall performance: shorter fixation corresponds with lower overall performance.

e.g., report the sum of the numbers, the AB effect was not observed. Therefore it is likely that the task-set preparation time may be reduced for a single goal.

With respect to dyslexia, it may be that the preparation of task-set is slow, with dyslexic readers (as a group) taking more than the maximum fixation duration of 800 ms. It might be that the preparation of task-set is not initiated until the onset of the RSVP sequence in dyslexic reader (again, as a group). Although not manipulated in dyslexia, foreperiod – the time period before the presentation of T1 – has been shown to influence the AB in non-selected samples of adults, with reduced effects at longer, predictable, or cued foreperiods (longer and predictable, Badcock et al. 2013; cued, Martens & Johnson 2005). Therefore there seems to be an influence of the temporal orienting of attention (for a review see Nobre, Correa & Coull 2007) in the AB which may also be a component of task-set.

In summary, it may be slow or incomplete development of task-set during the fixation period that influences overall dual-target accuracy in developmental dyslexia. Further empirical data is needed to test this suggestion.

6.2 T2 temporal position and variability

The temporal position of T2 was related to between-group effect-size for the dyslexic and typical readers. The maximum temporal position of T2 ($r = -.68$, $p < 0.05$) and the variability between the minimum and maximum temporal positions of T2 ($r = -.72$, $p < 0.05$) were negatively related to effect-size. This indicates that the longer the temporal distance between fixation and the presentation of T2, as well as the greater the variability in temporal position of T2, the less the difference between-groups.

These two variables are heavily confounded with each other ($r = .99$, $p < 0.01$). One explanation for the pattern is temporal orienting.

When attention can be directed to a particular point in time, decisions regarding a target are more accurate (again see Nobre, Correa & Coull 2007, for a review). This has also been demonstrated in the AB. When Martens and Johnson (2005) cued the temporal location of targets within an RSVP sequence, the AB was reduced. Similar reductions were found when Badcock et al. (2013) individually tailored foreperiod and made it predictable between trials: relative to when the temporal location of T1 was randomly selected between 250 and 750 ms, the AB was reduced. Further to this, Tang, Badcock, and Visser (2013) demonstrated that practice in the AB actually increased expectations about the temporal locations of the targets. This suggests that with exposure to RSVP tasks, observers are learning about the temporal locations of the targets. Therefore, if time periods were longer and more variable, the predictability of temporal locations would be more difficult. Under these circumstances, it might be that the task is more challenging for both dyslexic and typical readers, reducing the difference between-groups. In this sense, to maximise the difference between-groups, short and easily predicted (i.e. minimal variability) time periods should be selected. In a re-analysis of earlier data, Badcock et al. (2011) demonstrated that practice effects in the AB differentiated between the dyslexic and typically reading groups: where differences were apparent in the first half the experiment, the dyslexic readers had poorer performance, but not in the second half of the experiment.

In summary, there is evidence in support of slower learning in the AB in dyslexic readers (Badcock, Hogben & Fletcher 2011). Additional evidence suggests the temporal locations are learned during the AB (Tang, Badcock & Visser 2013). In combination, this evidence offers an explanation for the reduced between-group effect for dyslexia and typical readers in the AB with longer and more variable T2 temporal

locations. At longer and more variable T2 temporal locations, both groups have difficulties learning the temporal locations of the targets. At shorter and less variable T2 temporal locations, the dyslexic reading group has relatively more difficulty learning the temporal locations of the targets; therefore, the between group difference is due to enhanced performance in typical readers.

6.3 Stimulus Onset Asynchrony (SOA)

Longer SOAs were associated with smaller differences between the dyslexic and typical readers ($r = -.66$, $p > 0.05$). Although large in magnitude, this effect failed to reach significance. One of the reasons for this is that the distribution was positively skewed and predominantly driven by a single experiment in which the SOA was 133 ms. Therefore, we do not wish to place too much emphasis on this result but we do want to raise it for future consideration.

Di Lollo, Hanson, and McIntyre (1983) observed that children with dyslexia showed evidence of slower processing rates under conditions of backward masking. Backward masking certainly plays a role in AB processing, although it may serve the function of bringing performance off ceiling (Jannati et al. 2012; Jannati, Spalek & Di Lollo 2011). The work of Di Lollo et al. (1983) has been considered in the dyslexia and AB research but it has been dealt with via comparisons in a single-target task, rather than adaptive method as Di Lollo et al. used. That is, if the groups do not differ on a single-target task, then the sensitivity is matched. With respect to single-target tasks, the statistics usually indicate that there is no difference between dyslexic and typical readers (Badcock, Hogben & Fletcher 2008; Buchholz & Aimola Davies 2007; Laasonen et al. 2012; Visser, Boden & Giaschi 2004), and therefore sensitivity differences can be dismissed as an explanation for dual-target task group differences.

405 Accuracy rates in these single-target tasks are at ceiling, most likely hiding any group
406 differences. In fact, there is one study in which single-target performance was not at
407 ceiling and the dyslexic readers were statistically poorer in the single-target task
408 (McLean et al. 2010). Furthermore, when used as a covariate in the dual-target
409 analysis, the group difference was no longer significant. In light of this evidence,
410 future investigations should control for individual sensitivity to targets within the
411 dual-target paradigms, if for no other reason than to ensure that ceiling effects do not
412 influence results.

413 7. Further considerations

414 7.1 The Lacroix et al. anomalous result

415 There is one anomalous result in the AB and dyslexia literature. Lacroix et al. (2005)
416 reported better overall performance in their group of children (15-years of age) with
417 developmental dyslexia, relatively to typically reading peers. The above parameters
418 (fixation duration, temporal locations of T2, and SOA) do not offer any insight into
419 this finding, in fact, the fixation duration (800 ms) would predict the opposite effect in
420 light of the above discussion. Two pieces of information may be relevant. The sample
421 included children, and the stimuli (targets and distractors) were numbers. Buchholz
422 and Aimola Davies (2007) presented a similar design in adults. As well as their
423 results being in the typical direction (i.e. poorer performance in dyslexic readers), the
424 effect-size was five standard deviations from the mean of all effect-sizes examined in
425 this meta-analysis; recall that these results were excluded from the meta-analysis.
426 Lallier et al. (2010) found the typical pattern of results when number targets were
427 presented in number distractors in children (approximately 10-years of age), however,
428 the task required identification of T1 and detection of T2 which was always the

429 number zero. The other experiments involving children included random dot
430 distractors (McLean et al. 2010; Visser, Boden & Giaschi 2004) or no distractors
431 (Facoetti et al. 2008). Therefore, it seems that some combination of the sample age
432 group, the target-distractor relationship, and task-set may have some bearing on this
433 relationship.

434 As suggested by Lacroix et al. (2005), superior dual-target accuracy in the dyslexic
435 group may be explained by development differences in the depth of target processing.
436 Suppose the group with dyslexia have less detailed representations for numbers and
437 the group with typical reading have more detailed representations for numbers. If
438 greater resources were required to access the more detailed representations, the
439 typical readers would exhibit poorer performance. This may change with
440 development. As the retrieval of these representations becomes more automatic, the
441 effect may reverse, potentially as observed by Buchholz and Aimola Davies (2007) in
442 an adult sample. Furthermore, if the adults with dyslexia were slower to access these
443 representations they may also show greater interference from distractors from the
444 same category. However, this does not fit with the other adult research with letters as
445 targets and distractors (Badcock, Hogben & Fletcher 2008; Hari, Valta & Uutela
446 1999; Laasonen et al. 2012) or Lallier et al.'s (2010) findings.

447 One characteristic of these experiments is task-set: two involve the identification of
448 two targets (Buchholz & Aimola Davies 2007; Lacroix et al. 2005), whereas the
449 others involve the identification of T1 and the detection of an always known T2. This
450 constitutes a 'task-switch' and has been associated with a cost which is independent
451 of the AB effect (Potter et al. 1998). However, we are not aware that the difficulty of
452 identification-identification (id-id) versus identification-detection (id-det) conditions

453 have been assessed. It is the case that guessing T2 in an id-det paradigm would result
454 in 50% accuracy, whereas it would be lower in an id-id paradigm². Furthermore,
455 practice effects in the AB suggest that repeated targets become easier to process due
456 to acquired distinctiveness (Maki & Padmanabhan 1994); therefore, the id-det
457 paradigm may be less difficult, especially over time. If this were the case, id-det
458 paradigms may constitute easier task-sets, relative to id-id paradigms. Following these
459 assumptions, results from id-det paradigms (specifically Lallier, Donnadieu &
460 Valdois 2010) are difficult to compare with id-id paradigm (i.e. Buchholz & Aimola
461 Davies 2007; Lacroix et al. 2005).

462 We are left with questions concerning the comparability of id-id and id-det paradigms
463 as well as evidence from children and adults. Based on the current evidence we are
464 unable to settle on a conclusion. It is likely that task-set has an important role and
465 generalisation across samples at different developmental stages should be made
466 cautiously. As mentioned with respect to SOA, individually tailoring SOA would
467 overcome one of these difficulties. In the case of the Lacroix et al. (2005) evidence, it
468 may have been that individuals in this particular dyslexic group required shorter
469 SOAs on average relative to their age-matched peers to achieve equivalent levels of
470 accuracy. Tailoring SOA would overcome difference in the speed of access to the
471 target information, allowing for a comparison of the duration of this processing cost
472 on T2. Some strategies for adjusting SOA have been reported (Badcock et al. 2006;
473 Badcock et al. 2013).

² We thank Veronika Coltheart for this suggestion.

474 7.2 Confounded variables

475 There were significant inter-correlations between the variables, which are due to the
476 commonalities and differences between experiments. For example, the variables
477 indexing the temporal location of the first and second targets were highly correlated,
478 r-values greater than .8. Similarly, the number of distracter identities was significantly
479 related to the maximum and variability of temporal positions of the second target ($r =$
480 .93 and $r = .94$, both $p < .01$). With respect to the number of distracter identities, this
481 was highly – though not significantly – correlated with the between-group effect-size
482 ($r = -.74$, $p = .09$). This relationship also fits with an advantage for typical readers
483 learning to ignore a small distracter set (see Maki & Padmanabhan 1994 for the role
484 of distracter set in practice with the AB paradigm). However, the variables
485 highlighted in the results and discussion sections are based on the strength and
486 significance of relationships with between-group effect-size. Without direct
487 experimental manipulation of these variables, it cannot be determined whether the
488 highlighted variables are the critical factors. Therefore we have purposefully
489 restricted the considerations of the relationship between the highlighted variables and
490 reading mechanisms until such a relationship is demonstrated.

491 One suggestion arising from these confounds is that a common paradigm be adopted
492 for AB and dyslexia research. Considering the limited reliance on literacy experience
493 for shape-targets and random-dot distracters used by McLean et al. (2010) and Visser
494 et al. (2004), this seems like a good starting place. Furthermore, this paradigm has
495 also been used to evaluate the relationship between AB performance and typical
496 reading (La Rocque & Visser 2009; McLean et al. 2009), so there is a growing body
497 of evidence common to this target and distracter set related to reading.

7.3 Subtypes of dyslexia

We have not been able to address the subtypes of dyslexia in this meta-analysis and we want to flag this as an important consideration for future research. McLean et al. (2010) examined their results with respect to non-word and irregular word reading independently but did not find a difference with respect to the between group relationship. La Rocque and Visser (2009) found a relationship between non-wording reading and AB magnitude, suggesting some role of phonological processing. However, this specifically related to a between group interaction rather than an overall main effect, therefore it is not clear what role phonological processing would have for the current set of variables. A critical step in pinning down the relevance of any variable in relationship to dyslexia, is pinning down which particular component of the reading process, and in turn which subtype, the variable is associated with.

7.4 The available evidence

This research is limited by the available evidence. The number of experiments published in the literature is small, and exclusory criteria reduced this to 9 (6 for some variables) in the current meta-analysis. The dataset is limited to published work which may be associated with biases with respect to the publication of significant effects. The results should be interpreted with these limitations in mind.

8. Summary and Conclusion

In this paper we report on a meta-analysis of published AB experiments conducted in developmental dyslexia. We examined the common occurrence of an overall between-group difference where dyslexic readers exhibit lower target reporting accuracy in relation to task parameters which varied between and within experiments. This between-group difference was related to fixation duration, maximum and variability

523 of second target temporal location, and stimulus onset asynchrony. Future
524 investigations should consider the development of task-set, temporal learning, and the
525 influence of backward masking in the AB and dyslexia in order to best determine the
526 relationship between reading and the AB, and whether it may be a potential tool for
527 intervention.

528 9. Acknowledgements

529 This research was funded by the Australian Research Council Centre of Excellence in
530 Cognition and its Disorders (CE110001021) <http://www.ccd.edu.au>. The authors
531 would like to thank Veronika Coltheart for her comments on an earlier version of the
532 manuscript, Gen McArthur for her valuable input and support, as well as Sachiko
533 Kinoshita and Maree Tyson-Parry for their ears and thought provoking discussions.
534 We would also like to thank Marja Laasonen and Matt Dye for sharing details of their
535 research procedures.

PRISMA 2009 Checklist

Section/topic	#	Checklist item	Reported on page #
TITLE			
Title	1	Identify the report as a systematic review, meta-analysis, or both.	
ABSTRACT			
Structured summary	2	Provide a structured summary including, as applicable: background; objectives; data sources; study eligibility criteria, participants, and interventions; study appraisal and synthesis methods; results; limitations; conclusions and implications of key findings; systematic review registration number.	
INTRODUCTION			
Rationale	3	Describe the rationale for the review in the context of what is already known.	
Objectives	4	Provide an explicit statement of questions being addressed with reference to participants, interventions, comparisons, outcomes, and study design (PICOS).	
METHODS			
Protocol and registration	5	Indicate if a review protocol exists, if and where it can be accessed (e.g., Web address), and, if available, provide registration information including registration number.	
Eligibility criteria	6	Specify study characteristics (e.g., PICOS, length of follow-up) and report characteristics (e.g., years considered, language, publication status) used as criteria for eligibility, giving rationale.	
Information sources	7	Describe all information sources (e.g., databases with dates of coverage, contact with study authors to identify additional studies) in the search and date last searched.	
Search	8	Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated.	
Study selection	9	State the process for selecting studies (i.e., screening, eligibility, included in systematic review, and, if applicable, included in the meta-analysis).	
Data collection process	10	Describe method of data extraction from reports (e.g., piloted forms, independently, in duplicate) and any processes for obtaining and confirming data from investigators.	
Data items	11	List and define all variables for which data were sought (e.g., PICOS, funding sources) and any assumptions and simplifications made.	
Risk of bias in individual studies	12	Describe methods used for assessing risk of bias of individual studies (including specification of whether this was done at the study or outcome level), and how this information is to be used in any data synthesis.	
Summary measures	13	State the principal summary measures (e.g., risk ratio, difference in means).	
Synthesis of results	14	Describe the methods of handling data and combining results of studies, if done, including measures of consistency (e.g., I^2) for each meta-analysis.	

PRISMA 2009 Checklist

Section/topic	#	Checklist item	Reported on page #
Risk of bias across studies	15	Specify any assessment of risk of bias that may affect the cumulative evidence (e.g., publication bias, selective reporting within studies).	
Additional analyses	16	Describe methods of additional analyses (e.g., sensitivity or subgroup analyses, meta-regression), if done, indicating which were pre-specified.	
RESULTS			
Study selection	17	Give numbers of studies screened, assessed for eligibility, and included in the review, with reasons for exclusions at each stage, ideally with a flow diagram.	
Study characteristics	18	For each study, present characteristics for which data were extracted (e.g., study size, PICOS, follow-up period) and provide the citations.	
Risk of bias within studies	19	Present data on risk of bias of each study and, if available, any outcome level assessment (see item 12).	
Results of individual studies	20	For all outcomes considered (benefits or harms), present, for each study: (a) simple summary data for each intervention group (b) effect estimates and confidence intervals, ideally with a forest plot.	
Synthesis of results	21	Present results of each meta-analysis done, including confidence intervals and measures of consistency.	
Risk of bias across studies	22	Present results of any assessment of risk of bias across studies (see Item 15).	
Additional analysis	23	Give results of additional analyses, if done (e.g., sensitivity or subgroup analyses, meta-regression [see Item 16]).	
DISCUSSION			
Summary of evidence	24	Summarize the main findings including the strength of evidence for each main outcome; consider their relevance to key groups (e.g., healthcare providers, users, and policy makers).	
Limitations	25	Discuss limitations at study and outcome level (e.g., risk of bias), and at review-level (e.g., incomplete retrieval of identified research, reporting bias).	
Conclusions	26	Provide a general interpretation of the results in the context of other evidence, and implications for future research.	
FUNDING			
Funding	27	Describe sources of funding for the systematic review and other support (e.g., supply of data); role of funders for the systematic review.
