*Xenoposeidon proneneukos* is a sauropod dinosaur represented by a single partial dorsal vertebra, NHMUK R2095, which consists of the centrum and the base of a tall neural arch. Despite its fragmentary nature, it is recognisably distinct from all other sauropods, and is here diagnosed with five unique characters. One character previously considered unique is here recognised as shared with *Rebbachisaurus garasbae*: an “M”-shaped arrangement of laminae on the lateral face of the neural arch. Following the more complete *Rebbachisaurus garasbae*, these laminae are now interpreted as ACPL and lateral CPRL, which intersect anteriorly; and PCDL and CPOL, which intersect posteriorly. Similar arrangements are also seen in some other rebbachisaurid specimens (though not all, possibly due to serial variation), but never in non-rebbachisaurid sauropods. *Xenoposeidon* is therefore referred to Rebbachisauridae. Due to its elevated parapophysis, the holotype vertebra is considered a posterior dorsal despite its elongate centrum. Since *Xenoposeidon* is from the Berriasian–Valanginian (earliest Cretaceous) Ashdown Beds Formation of the Wealden Supergroup of southern England, it is the earliest known rebbachisaurid by some 10 million years. Electronic 3D models were invaluable in determining *Xenoposeidon*'s true affinities: descriptions of complex bones such as sauropod vertebrae should always provide them where possible.
Abstract

*Xenoposeidon proneneukos* is a sauropod dinosaur represented by a single partial dorsal vertebra, NHMUK R2095, which consists of the centrum and the base of a tall neural arch. Despite its fragmentary nature, it is recognisably distinct from all other sauropods, and is here diagnosed with five unique characters. One character previously considered unique is here recognised as shared with *Rebbachisaurus garasbae*: an “M”-shaped arrangement of laminae on the lateral face of the neural arch. Following the more complete *Rebbachisaurus garasbae*, these laminae are now interpreted as ACPL and lateral CPRL, which intersect anteriorly; and PCDL and CPOL, which intersect posteriorly. Similar arrangements are also seen in some other rebbachisaurid specimens (though not all, possibly due to serial variation), but never in non-rebbachisaurid sauropods. *Xenoposeidon* is therefore referred to Rebbachisauridae. Due to its elevated parapophysis, the holotype vertebra is considered a posterior dorsal despite its elongate centrum. Since *Xenoposeidon* is from the from the Berriasian–Valanginian (earliest Cretaceous) Ashdown Beds Formation of the Wealden Supergroup of southern England, it is the earliest known rebbachisaurid by some 10 million years. Electronic 3D models were invaluable in determining *Xenoposeidon*’s true affinities: descriptions of complex bones such as sauropod vertebrae should always provide them where possible.
**Introduction**

*Xenoposeidon proneneukos* is a neosauropod sauropod dinosaur from the Berriasian–Valanginian (earliest Cretaceous) Ashdown Beds Formation of the Wealden Supergroup of southern England. It is represented by a single partial mid-to-posterior dorsal vertebra, NHMUK R2095 (BMNH R2095 at the time of the original description by Taylor and Naish 2007). This element consists of the centrum and the base of a tall neural arch, broken off below the transverse processes and zygapophyses. Despite its fragmentary nature, it is recognisably different from all other sauropods, and Taylor and Naish (2007) diagnosed it on the basis of six characters that they considered unique among sauropods.

D’Emic (2012:651) asserted that “the absence of diagnostic features renders *Xenoposeidon* a nomen dubium”. However, his assessment was mistaken in several respects. For example, the extension of the base of the neural arch to the posterior extremity of the centrum is clearly not, as he asserted, due to damage. D’Emic claimed that dorsal vertebrae illustrated by Osborn and Mook (1921:plates LXIX and LXXII) have forward-sloping neural arches resembling those of *Xenoposeidon*: in reality, only one posterior dorsal vertebrae out of four complete dorsal columns illustrated in that monograph shows a forward slope, and it differs so much from its fellows that this can only be interpreted as the result of crushing. D’Emic further claimed that the lamina patterns observed in *Xenoposeidon* can be recognised in other sauropods, but I have been unable to find morphology resembling them in the descriptions he suggests: Osborn and Mook 1921 for *Camarasaurus*, Riggs 1903 for *Brachiosaurus* (probably a typo for Riggs 1904, which also does not depict similar patterns), Carballido et al. 2011 for *Tehuelchesaurus*. A similar pattern does appear in *Rebbachisaurus*, as will be discussed below. D’Emic (2012:651) is probably correct that the “asymmetric neural canal” described by Taylor and Naish (2007:1553–1554) is a misreading of the tall centroprezygapophyseal fossae as being the anterior portion of the neural canal: as Taylor and Naish pointed out, “The vacuity is filled with matrix, so the extent of its penetration posteriorly into the neural arch cannot be assessed”. Nevertheless, the shape and size of the fossa is unique among sauropods, and it is bounded by laminae which do not seem to be medial CPRLs. In summary, *Xenoposeidon proneneukos* is a valid, diagnosable taxon, contra D’Emic (2012).

Taylor and Naish (2007:1554–1557) compared the *Xenoposeidon* vertebra to those of the main neosauropod groups — Diplodocoidea, Camarasauridae, Brachiosauridae and Titanosauria — and concluded that it could not be convincingly referred to any of these groups. Their phylogenetic analysis (pp. 1157–1558 and figure 6) corroborated this by recovering *Xenoposeidon* as a neosauropod in all most parsimonious trees, but in a polytomy with all other neosauropods, wholly unresolved save that the clade Flagellicaudata was preserved in all MPTs.

In light of Wilson and Allain’s (2015) redescriptions of *Rebbachisaurus garasbae*, and the availability of more photographs and models of rebbachisaurid material, it has now become possible to reinterpret the idiosyncratic system of laminae found in *Xenoposeidon*, and to refer it confidently to an existing family-level clade.

**Anatomical Abbreviations**

- aEI — average elongation index *sensu* Chure et al. 2010: length of a centrum divided by the average of the height and width of the posterior articular surface.
• ACPL — anterior centroparaphyseal lamina.
• CPOL — centropostzygapophyseal lamina.
• CPRF — centroprezygapophyseal fossa.
• CPRL — centroprezygapophyseal lamina.
• EI — elongation index sensu Wedel et al. 2000: length of a centrum divided by the height of the posterior articular surface.
• PCDL — posterior centrodiapophyseal lamina.
• PCPL — posterior centroparaphyseal lamina.
• POSL — postspinal lamina.
• Postzyg — postzygapophysis.
• PPDL — paradiapophyseal lamina.
• Prezyg — prezygapophysis.
• PRPL — prezygaparaphyseal lamina.
• PRSL — prespinal lamina.
• SDL — spinodiapophyseal lamina.

Institutional Abbreviations

• IWCMS — Isle of Wight County Museum Service at Dinosaur Isle, Sandown, Isle of Wight, England.
• MIWG — Museum of Isle of Wight Geology (now Dinosaur Isle Visitor Centre), Sandown, Isle of Wight, England.
• MNHN — Muséum National d'Histoire Naturelle, Paris, France.
• “WN” — “without number”, an informal designation for specimens awaiting accession.

Reinterpretation

Taylor and Naish’s (2007) history, geography, geology and description of the Xenoposeidon specimen requires no revision, and should continue to be considered definitive: this paper does not supersede it, but should be read in conjunction with it.

The illustrations of the specimen in the original paper, however, were in monochrome and omitted the dorsal and ventral views. The present paper supplements these illustrations with a colour depiction from all six cardinal directions (Figure 1), and a high-resolution 3D model of the specimen (supplementary file AA).

More importantly, Taylor and Naish’s (2007) interpretation of some features of the vertebra, particularly the “M”-shaped complex of laminae on the lateral faces of the neural arch, was mistaken. Although the neural spine and dorsal part of the neural arch are missing, including the pre- and postzygapophyses and lateral processes, they wrote that “sufficient laminae remain to allow the positions of the processes to be inferred with some certainty”. But their inferences were incorrect. Taylor and Naish (2007:1553) interpreted the cross-shaped structure on the anterodorsal part of the left lateral face of the neural arch as the site of the parapophysis, despite the lack of any articular facet in that location. This influenced their interpretation of the four laminae that met at that point as the ACPL below, the PPDL above, the PRPL anteriorly and an
unnamed accessory infraparapophyseal lamina posteroventrally, which they interpreted as homologous with a PCPL (Figure 2A). Similarly, they did not attempt to identify either the long lamina running up the posterior edge of the lateral face of the neural arch (designating it only “posterior lamina”) or the lamina forming a shallow “V” with the “accessory infraparapophyseal lamina”, simply calling it an “accessory postzygapophyseal lamina” (Figure 2A).

Among the various unusual features of the *Xenoposeidon* vertebra, the “M”-shaped set of laminae is immediately apparent in lateral view (Figure 3A): a line can be traced from the anterior margin of the neural arch’s lateral face up the ACPL to the cross that was interpreted as the parapophysis, then posteroventrally down the “accessory infraparapophyseal lamina”, then posterodorsally up the “accessory postzygapophyseal lamina” and finally down the posterior margin of the neural arch’s lateral face, along the “posterior lamina”. Photographs of other specimens that were available to us at this time did not apparently manifest similar features.

But subsequent work on *Rebbachisaurus garasbae* (Wilson 2012:100, Wilson and Allain 2015) — and an associated video of the rotating vertebra (see acknowledgements) — show that *Rebbachisaurus* has a similar complex of laminae (Figure 3B), which are described by Wilson and Allain (2015:6) as the second of the eight autapomorphies that they listed for the species: “infrazygapophyseal laminae (lat. CPRL, CPOL) that intersect and pass through neighbouring costal laminae (ACPL, PCDL) to form an ‘M’ shape”.

Because the illustrated dorsal vertebra of *Rebbachisaurus* — MNHN MRS 1958 — is substantially complete, it is possible to follow the trajectories of the laminae that participate in the “M” to their apophyses, and so determine their true identities. The two vertically oriented laminae — the outer pillars of the “‘M’” — continue up past the top of the “‘M’”. The anterior one supports the parapophysis, and the posterior supports the diapophysis. And the two laminae that form the valley in the middle of the “‘M’” support the prezygapophyses and postzygapophyses: in both cases, as noted by Wilson and Allain, they intersect the vertical lamina before continuing to meet their respective zygapophyses. The four laminae that make up the “‘M’”, from anterior to posterior, are therefore the ACPL, posterior part of the lateral CPRL, anterior part of the CPOL and PCDL. Of these, the intersection between the ACPL and lateral CPRL is clearly visible in left lateral view of MNHN MRS 1958. The intersection between the CPOL and PCDL is less apparent in this view, though clear in three dimensions. Both laminae continue dorsally beyond this intersection, but their paths are somewhat changed at the point of contact, with the dorsal portion of the PCDL inclining more anteriorly, and the rod-like CPOL apparently passing through the sheet of bone formed by the PCDL to meet the postzygapophysis.

The referred *Rebbachisaurus garasbae* specimen NMC 50844 described and illustrated by Russell (1996:388–390 and figure 30) is also broadly consistent with this morphology. It is not possible to be definite about the laminar intersection based only on line drawings of the specimen from the four cardinal directions, but, as illustrated in Russell’s figure 30c, the lateral CPRL does appear to pass through the ACPL. The CPOL seems in this specimen to originate posterior to the PCDL, not intersecting with it. But this difference from the holotype dorsal may be serial variation since, as Russell notes, the relatively longer centrum of his specimen indicates a more anterior serial position than for the holotype’s dorsal vertebra; and this interpretation is corroborated by the observation than, based on lamina trajectories, the anteroposterior distance between the parapophysis and diapophysis was less in NMC 50844 than in the holotype.

In light of these *Rebbachisaurus* specimens, the mysterious laminae of *Xenoposeidon* are easily explained. It is now apparent that the cross on the side of the *Xenoposeidon* vertebra is not the site of the parapophysis, as Taylor and Naish (2007:1553) proposed, but merely the intersection
of two laminae that pass right through each other: the ACPL, running dorsolaterally, and the lateral CPRL, extending anterodorsally to the (missing) prezygapophysis (Figure 2B). Similarly, the “posterior lamina” is the PCDL, and it intersects with the CPOL, though the intersection is lost in NHMUK R2095 (Figure 2B). Both the parapophysis and diapophysis of the *Xenoposeidon* vertebrae would have been located some distance above the preserved portion, the former anterior to the latter.

It appears from Dalla Vecchia (1999:figure 47, left part) that in the holotype and only vertebra of *Histriasaurus boscarollii*, “WN-V6”, the CPOL on the right side of the vertebra intersects with the PCDL in the same way as in *Rebbachisaurus*, though it is not possible to determine whether the lateral CPRL similarly intersects the ACPL. Dorsal vertebrae of other rebbachisaurid sauropods, however, do not appear to feature the distinctive “M” and intersecting laminae of *Rebbachisaurus* and *Xenoposeidon*:

- The 3D model of a dorsal vertebra of *Nigersaurus* (Sereno et al. 2007) shows that the lateral CPRLs originate anterior to the ACPLs and the CPOLs posterior to the PCDLs, so that there is no intersection. A subtle “V” shape does appear high up on the lateral faces of the neural arch, between the ACPL and the PCDL, but it seems unrelated to the lateral CPRL and CPOL.

- Unpublished 3D models of an anterior dorsal neural arch and a more posterior dorsal vertebra of *Katepensaurus* (pers. comm., Lucio M. Ibicucci) as illustrated in figures 3A and 5A of Ibicucci et al. (2017) show that in both vertebrae, the lateral CPRLs originate anterior to the ACPLs, and the CPOLs seem to originate posterior to the PCDLs — though damage to the posterior portion makes the latter uncertain.

- The laminae do not appear to intersect in the illustrated dorsal vertebra of *Demandasaurus* (Fernández-Baldor et al. 2011:figure 9).

- The sole known vertebra of *Nopcsaspondylus* seems to have an entirely different pattern of lamination (Mannion 2010:figure 5) with no lamina intersections like those of *MNHN MRS 1958*.

No determination can be made for other rebbachisaurids as they are insufficiently preserved (e.g. *Limaysaurus*, *Amazonsaurus*), or illustrated (e.g. *Cathartesaura*), or simply lack posterior dorsal vertebral material (e.g. *Rayososaurus*, *Tataouinea*, *Comahuesaurus*, *Zapalasaurus*).

However, we cannot rule out the possibility that complete and well-preserved posterior dorsal vertebrae of most or all rebbachisaurids have *Rebbachisaurus*-like intersecting laminae: even in those species for which a well-preserved vertebra lacks them, this could be due to serial variation, with these features only fully developing in the most posterior dorsals. *Xenoposeidon*, then, resembles *Rebbachisaurus* in the possession of a distinctive “M” on the lateral face of the neural arch, in the intersecting lateral CPRL and ACPL, and in the elevation of the parapophysis above the level of the prezygapophysis — a complex of related features. Although at first glance they appear rather different, *Xenoposeidon* and *Rebbachisaurus*, while geometrically different, are topologically similar.

Regarding the significance of the elevated parapophysis, since no complete or nearly complete rebbachisaurid dorsal column has been described, comparisons with other, better represented sauropods are warranted. In the probable basal diplodocoid *Haplocanthosaurus*, the dorsal margin of the parapophyseal facet reaches the level of, and is coincident with, the prezygapophyseal facet around dorsal vertebra 7 or 8, but never rises any higher than this in more
posterior vertebrae (Hatcher 1903:plate I). In the more distantly related diplodocid diplodocoids _Apatosaurus_ and _Diplodocus_, the parapophysis never migrates far enough dorsally to reach a position level with the prezygapophyses, even in the most posterior dorsals (Gilmore 1936:plate XXV; Hatcher 1901:plates VII, VIII).

Taylor and Naish (2007:1554) argued that _Xenoposeidon_ could not at that time be convincingly referred to Rebbachisauridae because _Rebbachisaurus_ differs from NHMUK R2095 in five ways: “possession of a very prominent PCPL, large and laterally diverging prezygapophyses, depressions at the base of the neural arch (Bonaparte 1999:173), lateral foramina not set within fossae, and a strongly arched ventral border to the centrum.” Of these features, the first is now recognised as occurring in _Xenoposeidon_; the second appears to be an outright error, as the prezygapophyses of _Rebbachisaurus_ meet on the midline, and in any case the situation in _Xenoposeidon_ is not known. “Depressions at the base of the neural arch” seems to be a mistranslation of Bonaparte’s original Spanish, “profundas depresiones en la base de la espina neural”, which refers not to the neural arch but the neural spine, and since this portion is not preserved in _Xenoposeidon_, it is not informative for our purposes. The 3D model of the _Rebbachisaurus_ dorsal shows that in fact its lateral foramina are set in shallow depression, similar in quality if not in degree to those of _Xenoposeidon_. This leaves the stronger arching of the ventral border of the centrum in _Rebbachisaurus_, a feature that in isolation is not convincing.

In conclusion, the weight of morphological evidence supports including _Xenoposeidon_ within Rebbachisauridae. This is in accordance with the observation of Taylor and Naish (2007:1557), in whose phylogenetic analysis “various most-parsimonious trees also recover _Xenoposeidon_ in many other positions, including as a … rebbachisaurid.”

**Serial position**

The serial position of the _Rebbachisaurus garasbae_ holotype dorsal vertebra MNHN MRS 1958 is not definitely known. However, it has been uniformly referred to as a posterior dorsal, most likely due to the very elevated position of its parapophyses and Lavocat’s (1954) initial assessment of it as “une des dernières dorsales” (one of the last dorsals) — perhaps made with knowledge of the spatial relation of bones in the quarry.

The position of the _Xenoposeidon proneneukos_ holotype vertebra NHMUK R2095 is of course even more difficult to determine in light of the limited nature of the specimen, though its similarity to MNHN MRS 1958 suggests a similar position. Taylor and Naish (2007:1553) wrote that “the high position of the parapophysis on the neural arch of R2095 indicates a mid to posterior placement of the vertebra within the dorsal column, but, because the prezygapophyses must have been dorsal to it, it was probably not among the most posterior vertebrae in the sequence.” With the location of the parapophysis now interpreted as significantly higher than previously thought, and probably well above the prezygapophysis, an even more posterior position is indicated.

This posterior serial position is surprising in light of the anteroposterior length of the _Xenoposeidon_ centrum. Its posterior articular surface measures 160 mm high by 170 mm wide, while the length of even the preserved portion of the centrum is 190 mm, and it must have been at least 200 mm long when complete (Taylor and Naish 2007:table 1). As noted by Taylor and Naish (2007:1554), “the length of the centrum, especially in so posterior a dorsal vertebra, argues against [a diplodocoid identity]: the posterior dorsal centra of diplodocoids typically have EI < 1.0, compared with 1.25 for R2095” — or 1.21 using the aEI of Chure et al. (2010:384).

However, rebbachisaurids may be unusual among diplodocoids in this respect — perhaps
unsurprisingly, as they diverged early from the line leading to diplodocids, with their characteristically short dorsal centra, and likely retained something more similar to the ancestral neosauropod condition. Wilson and Allain (2015:8) give the centrum measurements of MNHN MRS 1958 as posterior height 231 mm, posterior width 220 mm and length 220 mm. This yields an aEI of 0.98, meaning that the *Xenoposeidon* centrum is only 24% more elongate than that of *Rebbachisaurus*. This is a significant difference, but not an outlandish one. For comparison, the centrum of the basal rebbachisaurid *Histriasaurus boscarolli* holotype “WN-V6” is relatively elongate, with its posterior articular surface measuring 150 mm high and centrum length of “more than 200 mm” (Dalla Vecchia 1998:122) yielding an EI of > 1.33. Also, the aEIs of the last four dorsal vertebrae of the *Brachiosaurus altithorax* holotype FMNH PR 25107 are 1.34, 1.27, 1.19 and 0.96 (calculated from the table of Riggs 1904:34): so aEIs of sauropod dorsals can vary, within two serial positions of the same individual, from values below that of MNHN MRS 1958 to above that of NHMUK R2095.

In conclusion, while the evidence regarding the serial position of NHMUK R2095 remains equivocal, it suggests a more posterior position than previous inferred — it can be fairly confidently described as “posterior” rather than “mid-to-posterior” — but it is unlikely to be the very last dorsal.

### Revised Reconstruction

In light of the reassignment of *Xenoposeidon* to Rebbachisauridae, and the reinterpretation of its laminae, I present a new reconstruction of how the vertebra NHMUK R2095 might have looked when complete (Figure 4). As in MNHN MRS 1958, the parapophysis and diapophysis are both elevated above the zygapophyses. The lateral CPRL and ACPL meet at at a point where they project outwards about the same distance from the vertebra, as is apparent from the preserved portion of the vertebra; but the CPOI is assumed to pass through a sheet-like PCDL as in *Rebbachisaurus*, because it is clear from breakage in NHMUK R2095 that the PCDL extended further from the body of the neural arch than the preserved portion indicates. The neural spine, composed as in *Rebbachisaurus* of pre- and post-spinal laminae together with the left and right SDLs, is shown fading out at the top, as there is no way to determine its height. The condyle that is the centrum’s anterior articular surface is reconstructed as only slightly convex, as in *Rebbachisaurus*.

It is instructive to compare this with the original reconstruction of the vertebrae (Taylor and Naish:figure 5). The new reconstruction has a taller neural arch, a far more elevated parapophysis, a more posteriorly located diapophysis (no longer dorsal to the parapophysis) and a shallower condyle, as that of the original reconstruction was drawn with those of brachiosaurs in mind.

### Systematic Palaeontology

Dinosauria Owen, 1842  
Saurischia Seeley, 1888  
Sauropodomorpha Huene, 1932  
Sauropoda Marsh, 1878  
Neosauropoda Bonaparte, 1986  
Rebbachisauridae Sereno et al., 1999  
*Xenoposeidon* Taylor and Naish, 2007
Xenoposeidon proneneukos Taylor and Naish, 2007

Holotype. NHMUK R2095, the Natural History Museum, London. A mid posterior dorsal vertebra consisting of partial centrum and neural arch.

Revised diagnosis: Differs from all other sauropods in the following characters:

1. neural arch covers dorsal surface of centrum, with its posterior margin continuous with that of the centrum;
2. neural arch slopes anteriorly 35 degrees relative to the vertical;
3. broad, flat area of featureless bone on lateral face of neural arch;
4. very large, teardrop-shaped centroprezygapophyseal fossa.
5. arched laminae form vaulted boundary of centroprezygapophyseal fossa.

The “arched laminae” of #5 are not the medial CPRLs, as these arise from the neural arch pedicels — and the laminae arising from the pedicels cannot instead be regarded lateral CPRLs, as those laminae are located on the lateral face of the neural arch, intersecting with the ACPLs. Furthermore, the point where the supporting laminae meet at the top of their arch is located some way posterior to the inferred location of the prezygaphyses (Figure 5).

Discussion

Age

As shown by the Wilson and Allain (2015:table 1), the 19 then-recognised rebbachisaurids (of which 13 had been named) span the middle third of the Cretaceous. The earliest recognised taxon is Histriasaurus boscarollii from the upper Hauterivian or lower Barremian limestones of southwest Istria, Croatia. Seven taxa, of which five are named, survived at least to the Cenomanian (earliest Late Cretaceous), of which two (Katepensaurus goicoecdeai and Limaysaurus tessonei) may by from the Turonian age.

As discussed by Taylor and Naish (2007:1547–1548), the precise location and horizon where NHMUK R2095 was excavated was not recorded in the specimen’s original brief description, which only said “the Wealden of Hastings” (Lydekker 1893:276). However, records of the collection of Philip James Rufford, who collected the specimen, indicate that the most likely location is Ecclesbourne Glen, a mile or two east of Hastings, East Sussex (see discussion in Taylor and Naish 2007:1548). The units exposed at Ecclesbourne Glen are part of the Ashdown Beds Formation, which straddles the Berriasian/Valanginian boundary; but the part of the formation at that location is from the earlier Berriasian age. If this assessment is correct, then Xenoposeidon is from the very earliest Cretaceous, giving it an age of around 140 million years — about 10 million years earlier than Histriasaurus.

This early age is consonant with a basal position within Rebbachisauridae, a possibility that is corroborated by Xenoposeidon’s camerate internal morphology compared with the camellate centra of most rebbachisaurids. However, further material will be required before numerical phylogenetic work can firmly establish its position within the group.
Wealden Rebbachisaurs

Although *Xenoposeidon* is the first named Rebbachisaurid from the Wealden Supergroup of southern England, other material from this unit has been referred to Rebbachisauridae. Naish and Martill (2001:plate 36, opposite page 236) illustrated some isolated sauropod teeth IWCMS.2001.201–203, and these were referred to Rebbachisauridae by Sereno and Wilson (2005:174). Mannion (2009) described a partial rebbachisaurid scapula MIWG 6544. Finally, Mannion et al. (2011) described a proximal caudal neural arch MIWG 5384, which they also interpreted as rebbachisaurid. All of these specimens are from the Barremian Wessex Formation of the Isle of Wight, so they could all belong to the same species or genus. However, since the likely Berriasian age of NHMUK R2095 makes it 10–15 Mya older than these specimens, it is unlikely that they belong to *Xenoposeidon*, but to some other as yet-unnamed rebbachisaurid. Thus is is likely that the Wealden Supergroup contains at least two rebbachisaurid sauropods.

3D models of complex bones

Electronic 3D models were invaluable in determining *Xenoposeidon*’s true affinities. Most obviously, the model of the *Xenoposeidon* vertebra itself, created by Heinrich Mallison, has functioned as an invaluable proxy for the fossil itself when I am unable to visit the NHMUK, and I have consulted it many times in writing this paper. I would also have been unable to determine to my own satisfaction whether the *Katepensaurus* dorsals feature intersecting laminae like those of *Rebbachisaurus* without the models provided by Lucio M. Ibiricu. Although no true model is available for the *Rebbachisaurus* dorsal itself or for the dorsal vertebrae of *Nigersaurus*, rotating videos were crucial in enabling me to understand their morphology. When interpreting specimens for which no such models exist, such as Russell’s (1996) referred *Rebbachisaurus* specimen NMC 50844, the conclusions reached using only 2D representations — whether photographs or drawings — are much less well founded.

Techniques such as photogrammetry (see e.g. Falkingham 2012; Mallison and Wings 2014) are reducing the barriers to the creation of high-quality 3D models in full colour. Doing so is now inexpensive in both time and money. In light of our discipline’s goal of making palaeontology more accessible and reproducible, then, it should become increasingly routine in the 21st Century to provide 3D models as a standard part of the description of complex bones such as sauropod vertebrae.

Acknowledgements

I thank Sandra D. Chapman (Natural History Museum, London) for access to the *Xenoposeidon* specimen, and Heinrich Mallison (Palaeo3D) who went far beyond the call of duty in building the 3D model of NHMUK R2095 and talking me through aspects of photogrammetry. I am also grateful to Jeff Wilson (University of Michigan) and Ronan Allain (Muséum National d'Histoire Naturelle, Paris) for sharing high-resolution photographs of the French *Rebbachisaurus* vertebra, and to Mathew J. Wedel (Western University of Health Sciences) and Darren Naish (University of Southampton) for helpful discussion. Lucio M. Ibiricu kindly provided access to unpublished 3D models of an anterior dorsal neural arch and a more posterior dorsal vertebra of *Katepensaurus*.

As noted in Taylor (2015), this project began when I recognised the true identity of the curious laminae on the *Xenoposeidon* vertebra while viewing a rotating video of the *Rebbachisaurus garasbae* holotype dorsal vertebra MNHN MRS 1958 on the University of Michigan Museum of...
Paleontology’s UMORF web-site (University of Michigan Online Repository of Fossils) at https://umorf.ummp.lsa.umich.edu/wp/gallery/vertebrate-animations/. This video was based on a 3D reconstruction created from CT scans performed at the AST-RX (Accès Scientifique à la Tomographie à Rayons X) of the MNHN by F. Goussard.

**Figure Captions**

**Figure 1.** NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos*, shown from all six cardinal directions. Top row: **A.** dorsal view, with anterior to the left. Middle row, left to right: **B.** anterior, **C.** left lateral, **D.** posterior and **E.** right lateral view. Bottom row: **F.** ventral view, with anterior to the left. Scale bar = 200 mm.

**Figure 2.** NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos*, in left lateral view, with interpretative drawing. **A.** The incorrect interpretation of the laminae from Taylor and Naish (2017:figure 4A), with identifying captions greyed out since they are largely incorrect. **B.** The revised interpretation of the same laminae, based on the similar arrangement in *Rebbachisaurus garasbae*. Scale bar = 200 mm.

**Figure 3.** Centra and neural arches of posterior dorsal vertebrae from two rebbachisaurid sauropods (not to scale), highlighting the distinctive “M” shape formed by laminae high on the
neural arch. **A.** NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos.*

**B.** MNHN MRS 1958, a posterior dorsal vertebra from the holotype specimen of *Rebbachisaurus garasbae.*

**Figure 4.** NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos,* in left lateral view, interpreted as a rebbachisaurid. This interpretation is modelled primarily on MNHN MRS 1958, a posterior dorsal vertebra from the holotype specimen of *Rebbachisaurus garasbae.* The CPOL passes through a sheetlike PCDL, as in *Rebbachisaurus*; but the lateral CPRL forms a cross-shaped junction with the ACPL, each of these laminae equally interrupting the trajectory of the other. Abbreviations as used in the text. Scale bar = 200 mm.

**Figure 5.** NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos,* in left anteroventrolateral view, highlighting the three sets of laminae related to the prezygapophyses. The trajectories of the medial CPRLs (which emerge from the neural arch pedicels) and the lateral CPRLs (which intersect with the APCLs) indicate the approximate position of the prezygapophyses. The additional arched laminae form the margins of the large, teardrop-shaped CPRF, but meet at a position some way below and posterior to the presumed location of the prezygapophyseal facets. Breakage of both medial CPRLs and the left ACPL and PCDL is indicated by cross-hatching. Note that, from this perspective, the lateral CPRL appears to turn a corner where it intersects with the ACPL, such that the posteroventral portion of the lateral CPRL appears contiguous with the dorsal portion of the ACPL. This is an illusion brought about by the eminence at the point of intersection. As always, this is much easier to see in three dimensions. Abbreviations as used in the text.

**Supplementary Files**

**Supplementary file 1.** Three-dimensional surface model (11 million polygons) of NHMUK R2095, the holotype and only vertebra of *Xenoposeidon proneneukos.* A 3D polygon mesh file was created by Heinrich Mallison in Agisoft Photoscan Pro version 1.3.0 (agisoft.com), from 95 high resolution digital photographs by the author. All 95 images aligned, and resulted in a dense point cloud at maximum resolution of 20,900,043 points and 44,871,128 polygons. Scaling was based on a single 10 cm scale bar created from a high quality scale bar placed in the pictures with the specimen. Available from [https://doi.org/10.6084/m9.figshare.5605612.v2](https://doi.org/10.6084/m9.figshare.5605612.v2)
