6

7 **ABSTRACT**

8 Insects have been used as an exemplary model in studying longevity, from extrinsic mortality  
9 pressures to intrinsic senescence. In the highly eusocial insects great degrees of variation in lifespan  
10 exist between morphological castes in relation to extreme divisions of labour, but of particular  
11 interest is the primitively eusocial orders. These species represent the ancestral beginnings of  
12 eusociality, in which castes are flexible and based on behaviour rather than morphology. Here we  
13 present data on the longevity of the primitively eusocial Neotropical paper wasp *Polistes canadensis*,  
14 in a captive setting removed of all environmental hazards. In comparison to other eusocial wasps' *P.*  
15 *canadensis* had an average lifespan of 193±10.5 days, with one individual living longer than 450  
16 days. Although this is shorter than most highly eusocial bee and ant queens. Natal colony variation  
17 does exist between *P. canadensis* colonies, possibly due to nutritional and genetic factors. This study  
18 provides a foundation for future investigations on the effects of intrinsic and extrinsic factors on  
19 longevity in primitively eusocial insects, as well as the relationship with caste and genome.

20

21

## 22 Introduction

23           Death comes to all, yet many seemingly ordinary insects have evolved some of the most  
24 dramatic and extraordinary lifespans, delaying the call of death for remarkable periods (Finch, 1990).  
25 Variation in insect longevity spans from *Ephemera simulans* males that live as adults for just 1.6 days  
26 (Carey, 2002) to the ants *Pogonomyrmex owyheeii* and *Lasius niger* whose queens can live up to 30  
27 years (Porter *et al.*, 1988; Hölldobler *et al.*, 1990). Interestingly, eusocial insects such as ants, wasps  
28 and bees feature heavily as examples of long-lived insects, but great variation exists not only  
29 between these species but also within species and even among genotype. We understand little  
30 about the roles of ecology, evolution, life-history and environment in generating variation in  
31 longevity in social insects, largely due to the difficulty of disentangling intrinsic life-span (hence-forth  
32 referred to as longevity) from survival (the abiotic and biotic environment pressures *i.e.* extrinsic  
33 mortality) on individuals (Hölldobler & Wilson, 1990; Keller, 1998; Keeler, 2014; Giraldo & Traniello,  
34 2014).

35           Eusocial insects are one of the most dominant, prolific, and diverse groups of organisms on  
36 the planet (Wilson, 1975). Much of this groups' success is attributed to the division of labour within  
37 the colony in the form of castes, with few or a single reproductive individual (*queen*), supported by  
38 tens to millions of non-reproductive individuals (*workers*) that forage, provision and care for sibling  
39 brood (Crespi, 1993). Caste fate is primarily determined by environmental conditions, e.g. nutrition  
40 during larval development, and occasionally genetic biasing (Oster & Wilson, 1978; Hölldobler &  
41 Wilson, 1990; Hughes *et al.*, 2003). Level of social complexity appears to be an important predictor  
42 of longevity in the eusocial insects. Within species variation in longevity can be pronounced between  
43 castes with queens living as much as 100-fold longer than their related workers (Ridley, 1993; Keller  
44 & Genoud, 1997; Kramer & Schaible, 2013). This is a remarkable example of a how a single genome  
45 can display plasticity in aging (Keller, 1998; Fjerdingstad & Crozier, 2006; Keeler, 2014). Few  
46 individuals are selected to specialise in egg production and therefore colony survival is likely to be

47 highly associated with and dependent on queen longevity (in the absence of reproductive  
48 succession, see (Bourke, 2007)). These long-lived queens live deep within the nest, sheltered from  
49 extrinsic pressures such as predation (Porter & Jorgensen, 1981; Keller & Genoud, 1997). Assuming  
50 there are costs associated with longevity, there may be selection for short lifespan in workers, and  
51 long-life span in queens, especially in highly eusocial species where colonies are large enough to  
52 support highly specialised, short-lived workers (Evans, 1958; Carey, 2001; De Loof, 2011; Ferguson-  
53 Gow *et al.*, 2014). Castes are unlikely to have been selected for such differential in the primitively  
54 eusocial species, where colonies are small each worker is valuable, and longevity of workers may be  
55 highly variable depending on the type or frequency of task each individual performs (Strassmann,  
56 1985).

57         Group size may influence worker longevity and this is likely to be due to the changes in  
58 nutrition that developing brood receive through the colony cycle (Matsuura *et al.* 1990; Schmid-  
59 Hempel 1998). At the colony level, the first worker brood display a shorter lifespan than those  
60 produced later in the colony cycle, and this may be due to the increase in levels of nutrition available  
61 to brood as the colony grows (Oster & Wilson, 1978; Porter & Tschinkel, 1986). Productivity is  
62 therefore maximised when number of workers, and consequently rates of nutritional acquisition, are  
63 low in the early stages of the colony establishment (Oster & Wilson, 1978; Porter & Tschinkel, 1985;  
64 Hölldobler & Wilson, 1990). As the colony grows, the ratio of workers to larvae often increases, and  
65 the larvae will benefit from increased quality and quantity of food, which can result in longer adult  
66 life-spans (e.g. in honey bees: Groot, 1953; Eischen, 1982). To date there have been no studies on  
67 how worker longevity varies with colony size in primitively eusocial insects. We predict the same  
68 patterns will occur, as in the highly eusocial species, since workers emerging early in the colony cycle  
69 are subject to low worker:larvae ratio and therefore low quality nutrition. Conversely, those  
70 emerging late in the colony cycle experience high worker:larvae ratio and thus high quality nutrition  
71 (Sumner *et al.*, 2007).

72 Group identity may also influence longevity. This may be due to a genetic effects (VanRaden  
73 & Klaaskate, 1993; Herskind *et al.*, 1996; Vollema & Groen, 1996; Klebanov *et al.*, 2001; Sebastiani *et*  
74 *al.*, 2012; Gems & Partridge, 2013), for example a genetic propensity to favour heavy or light feeding  
75 of larvae may translate into variable longevity of the resulting workers. Alternatively, the intrinsic  
76 environment of the group may influence longevity, for example through epigenetic effects (Keller &  
77 Jemielity, 2006; Yan *et al.*, 2014). If group effects are important, we predict that variation in  
78 longevity will be greater between groups than within groups, even in the face of group size variation.

79 Here we provide primary data on longevity of females in captive colonies of the predatory  
80 and primitively eusocial Neotropical *Polistes canadensis* paper wasps. Primitively eusocial species  
81 such as those of paper wasp genus *Polistes*, have been used to extensively study the evolution of  
82 eusociality, with their lack of morphological differences and plasticity in caste (Turillazzi & West-  
83 Eberhard, 1996). Yet, there are few systematic attempts to quantify longevity, and variation of, in  
84 this well-studied genus. Tropical species lack major seasonal constraints on longevity (Clutton-Brock,  
85 1991) and so offer an excellent system for testing the influence of ecology, evolution and  
86 environment on longevity, in the absence of seasonal curtailment of longevity. Studying insect  
87 lifespans in captivity, in the absence of predation and parasitism, is a valuable approach that allows  
88 us to quantify longevity in the absence of extrinsic mortality pressures (Chapuisat & Keller, 2002). .  
89 We compare our data with estimates of longevity in other eusocial insects to determine the  
90 importance of level of sociality and ecology (Hypothesis 1). We quantify the effects of colony identity  
91 on worker longevity (Hypothesis 2). We then conduct manipulation experiments to determine the  
92 influence of group size on worker longevity (Hypothesis 3). Understanding variation in longevity in  
93 these organisms provides an excellent foundation to explore similar questions in the higher-order  
94 social vertebrates (Carey, 2001).

## 95 **Methods**

96           *Collection:* Ten colonies of the paper wasp, *Polistes canadensis* were collected from the  
97 Republic of Panamá in August 2013 for transportation. Adult wasps were captured with full nest  
98 carton containing brood (eggs, larvae, and pupae) during dusk. Nest cartons and wasps were  
99 transferred to individual containers (150mmx150mmx150mm) with wire mesh ventilation. Colonies  
100 were provided with sugar solution and water *ad libitum* during transfer to the United Kingdom.  
101 Turnaround from capture to settled maintenance in the laboratory was 48 hours.

102           *Maintenance:* Nests were housed in clear transparent acrylic containers  
103 300mmx330mmx340mm each with two 525mm perimeter ventilation ducts (Figure 1). Food  
104 consisting of liquid cane sugar and live wax moth larvae *Achroia grisella*, along with distilled water  
105 and nest-building materials (cardboard & paper) were all supplied *ad libitum*. All sugar and food was  
106 obtained in batches and randomly split between colonies to ensure equal food quality provided to  
107 the adults to prevent any longevity variability as a result of adult nutrition (Johanowicz & Mitchell,  
108 2000; Harvey et al., 2012). In addition to food, nest-boxes were also given artificial planting for  
109 environmental enhancement, to provide shelter from female aggression for males (Polak, 2010).  
110 Nest boxes were cleaned regularly and without disturbing wasps or nest. Natural conditions from  
111 the collection sites were mimicked with temperatures of  $25\pm 1^{\circ}\text{C}$ ,  $70\pm 5\%$  relative humidity, and a  
112 light cycle of 12h light (12h dark).

113           *Data collection:* Colonies were monitored and wasp deaths recorded weekly. Any dead  
114 adults found were immediately removed from the nest box. Recording continued until all individuals  
115 deceased. Only adult wasps that developed in the wild were monitored for longevity. This ensured  
116 our adult wasps developed under natural nutritional conditions. Since all nests were collected from  
117 the same field site at the same time, local environmental conditions for development are controlled  
118 for as best as possible, though the colonies will differ from each other genetically.

119 Because we do not know the eclosion date for each adult wasp, our measures of longevity will be  
120 underestimates.

121 **Hypothesis 1: If adult longevity correlates with level of social complexity, we expect mean adult**  
122 **longevity of *P. canadensis* to be more similar to that of other *Polistes* species than the more highly**  
123 **eusocial insects.** Peer reviewed articles describing the longevity of eusocial Hymenoptera were  
124 collated to determine the longevity of species (and caste when described) -  
125 <https://webofknowledge.com/>. The average longevity of *P. canadensis*, as found in this study was  
126 included for comparison.

127 **Hypothesis 2: Colony identity (e.g. genotype) explains variance in mean female longevity in *P.***  
128 ***canadensis*.** Using the data generated from colonies M1-M7, variance in longevity between colonies  
129 was quantified to determine whether colony identity (and by extension, genotype,) explains  
130 variation in wasp longevity better than colony size.

131 **Hypothesis 3: Group size influences mean female longevity in *P. canadensis*.** Three colonies (M8,  
132 M9, M10) were monitored every 10 days for a period of 3 months, at which point their group sizes  
133 were of 28, 23 and 23 workers respectively. Each colony was then split, and randomly allocated  
134 between two new nest boxes (remaining with their related groups), giving six new groups in total  
135 and consisting of 18, 13, 12, 8, 8 and 9 females. A non-natal male was added to each new colony so  
136 that females had the opportunity to mate. These colonies were then maintained as above with wasp  
137 deaths monitored weekly for 220 days at which point all individuals were deceased.

138

139 *Statistical analyses:* Differences in adult survival were analysed using a Cox proportional hazards  
140 regression model where colony was used as a factor. Where differences in survival were found,  
141 pairwise comparisons between nests were made using Kaplan-Meier models with the Breslow  $\chi^2$   
142 statistic to highlight specific patterns between the colonies.

143 **Results**

144 **Hypothesis 1: The mean adult longevity of *P. canadensis* will be similar to that of other *Polistes***  
145 **species but differ from those observed in highly eusocial hymenopterans such as ants and bees.**

146 Literature suggests that the average lifespan of wasps can range from a maximum of 209 days in  
147 *Polistes lanio* down to 14 days in *Polistes exclamans*, with both studies carried out on wild *Polistes*  
148 colonies and so unable to account for extrinsic mortality (Strassmann, 1985; Giannotti & Machado,  
149 1994). The life-span of wasps in more highly eusocial species ranges from 59 days in *Vespa vulutina*  
150 to 14.5 days in both *Vespula germanica* and *Dolichovespula consobrina* (Akre, 1982; Dazhi &  
151 Yunzhen, 1989). Here found that 57% of adult *P. canadensis* colonies maintained in the lab can  
152 survive beyond 365 days with all but one colony having died after 450 days, providing data on  
153 longevity for 143 wasps in total (Figure 2) On average wasps lived for  $193 \pm 10.5$  days with one  
154 individual still alive after 450 days (Figure 3C; Figure 7).

156 **Hypothesis 2: Colony identity (e.g. genotype) explains variance in mean female longevity in *P.***  
157 ***canadensis*.**

158 Colony identity has a significant influence on adult wasp longevity (Cox proportional hazard survival  
159 analyses Wald = 17.134, d.f. = 6, P = 0.009 (Figure 3A-D, Table S1-2)).

161 **Hypothesis 3: Group size influences mean female longevity in *P. canadensis*.** .

162 Group sizes ranged from 9 (M5) to 34 (M7) wasps with average longevity within different nests  
163 ranging from  $130 \pm 39.4$  days (in M5) up to  $206 \pm 41.3$  days (in M6). Comparing the mean adult  
164 longevity of colonies M1-M7 against their original size gives no clear association (Figure 6A).  
165 Colonies M8-M10 showed no difference in survival prior to splitting (Wald = 4.016, d.f. = 2, P =  
166 0.134; Figure 4). However, after splitting into 6 cohorts of variable size, females exhibited

167 significantly different longevities (Wald = 12.544, d.f. = 5, p = 0.028; Figure 5). Pairwise analyses  
168 show this is likely due to cohort M8A (the largest) living significantly longer than most other cohorts  
169 (Figure 5D, Table S3-S4). Variation could not be attributed to natal colony identity. Cohorts from M9  
170 (M9A & M9B) and from M10 (M10A & M10B) show no significant difference in adult longevity within  
171 natal colony identity ( $\chi^2 = 0.173$ , P = 0.677;  $\chi^2 = 0.394$ , P = 0.530 respectively), cohorts from colony  
172 M8 (M8A & M8B) do differ from each other and are, incidentally, the 2 cohorts with the largest size  
173 difference ( $\chi^2 = 3.829$ , P = 0.05; Table S6). Group size shows a positive trend with longevity (Figure  
174 6B).

### 175 **Discussion**

176 Here we show *Polistes canadensis* to have the greatest longevity of any wasp recorded under  
177 laboratory conditions to date, and 2<sup>nd</sup> greatest overall, with wasps living on average 193 days, and  
178 up to 450 days. Our analyses suggest that colony identity and group size explain the variation in  
179 longevity, as predicted by our hypotheses. We discuss the implications of this data in the context of  
180 other species and ecology and evolution of eusociality.

181         Despite not monitoring the wasps from their day of eclosion (survival will be longer than our  
182 data shows), *P. canadensis* that developed in the wild have an average longevity of 193 days when  
183 maintained in the lab, free of extrinsic mortality pressures. This exceeds previous lifespan estimates  
184 on *Polistes* species where workers live approximately one month (Miyano, 1980; Strassmann, 1985;  
185 Giannotti & Machado, 1994; Giannotti, 1997, 2012; Gamboa, Greig & Thom, 2002; Torres, Gianotti &  
186 Antonialli-Jr, 2013). There was no obvious difference in longevity between the ‘worker force’ and the  
187 queens (defined by egg-laying). Instead we observe large cohorts of long lived individuals in multiple  
188 colonies. The average longevity found is also greater than the survival of queens in many other wasp  
189 species. This lack of differences between the castes may be, in part, a result of the biology of *Polistes*  
190 wasps which are a primitively eusocial species with all members able to reproduce and perform like  
191 a queen. Their eusocial structure is based on behaviour rather than the physiological constraints

192 observed in higher hymenopterans such as honey bees and many ants, which incidentally display the  
193 largest longevity disparities.

194 Colony identity was a clear predictor of wasp longevity. All colonies were collected at the  
195 same time from the same field site where adults on all nests would have shared the same  
196 developmental and environmental conditions. The potential causes for the effect of colony identity  
197 could be: 1) Genetic differences between the colonies. Genetic influences on longevity have been  
198 found in a number of model species from mammals to nematodes and insects (VanRaden &  
199 Klaaskate, 1993; Herskind et al., 1996; Vollema & Groen, 1996; Klebanov et al., 2001; Sebastiani et  
200 al., 2012; Gems & Partridge, 2013) and evidence for heritability of increased longevity in the insect  
201 fruit fly and honey bees have been observed (Rinderer, Collins & Brown, 1983; Luckinbill & Clare,  
202 1985) with some gene expression patterns being associated with longevity in queen honey bees  
203 (Corona et al., 2005). 2) Queen 'quality' which can be the result of extrinsic or intrinsic factors.  
204 Variation in fecundity of reproductive and dominance over other individuals in a colony is known as  
205 Queen quality and this can vary between queens (Harris & Beggs, 1995; Liebig, Monnin & Turillazzi,  
206 2005; Holman, 2012). This queen quality variation can be inherited (Rinderer & Sylvester, 1978;  
207 Corona et al., 2005) or driven by environmental factors (Hatch, Tarpay & Fletcher, 1999; Tarpay et al.,  
208 2011). 3) Unobserved differences in extrinsic factors that the nests had experienced before  
209 collection. Since the colonies were not monitored for their entire history, there is the possibility that  
210 something affected each one differently in order to cause varying longevity within their workers.  
211 What we can conclude is that although colony identity was a predictor of longevity in the adult  
212 wasps, this did not correlate with wasp size, and so suggests that the explanation that larger colonies  
213 would produce longer lived workers due to enhanced nutrition during larval development is not  
214 correct. When groups of sister wasps were manipulated into varying group sizes, the effects of  
215 group size on longevity was diluted and an association with group size and longevity was observed.

216 To investigate the underlying variation in longevity in eusocial insects, data from captive  
217 colonies a range of eusocial insects is required. Predatory eusocial insects such as wasps are  
218 underrepresented in the literature. Here, for the first time we quantify longevity of adult *P.*  
219 *canadensis* in the absence of extrinsic mortality and provide some tantalising support for the link  
220 between group size and adult longevity. Our results suggest predictions founded on previous  
221 research using higher eusocial species such as honeybees may not be relevant to primitively eusocial  
222 species. A particular challenge will be for future studies to also control for all of the described  
223 extrinsic and intrinsic factors such as wild nest site condition. It is clear that *P. canadensis* adults can  
224 live for unexpectedly long periods with the oldest individual being at least 450 days old.

225

394 Haigh & Spooner-Hart, 2013)

395

396 **Figure 3.** Survival of adults in seven *Polistes canadensis* colonies shown as raw numbers (A) and  
397 proportions (B) over a period of 15 months post capture whilst maintained under laboratory  
398 conditions. Their longevity estimates of adult wasps for each colony as estimated by Kaplan-Meier  
399 survival analysis (C) with pairwise differences as calculated by the Breslow statistic shown by capped  
400 horizontal bars (D)

401

402 **Figure 4.** Survival of adults in three *Polistes canadensis* colonies (92 adults) shown as raw numbers  
403 (A) and proportions (B) over a period of 80 days post capture whilst maintained under laboratory  
404 conditions, along with the survival estimates for each colony as estimated by Kaplan-Meier survival  
405 analysis (C) Estimations used in C-D are limited to the largest survival time due to censorship.  
406 Standard error bars in (D) calculated by Kaplan-Meier model.

407

408 **Figure 5.** Survival of 72 adult *Polistes canadensis* in 6 conspecific groups split from 3 colonies, shown  
409 as raw numbers (A) and proportions (B) over a period of 220 days post split whilst maintained under  
410 laboratory conditions. The survival estimates of these as estimated by Kaplan-Meier survival analysis  
411 are shown (C) with pairwise differences as calculated by the Breslow statistic shown by capped  
412 horizontal bars (D)

413

414 **Figure 6.** Associations between colony size and mean longevity of adult *P. canadensis* when  
415 maintained in original colony (A) or when manipulated into cohorts of varying size (B). Standard  
416 error bars calculated by Kaplan-Meier model.

417

418 **Figure 7.** Individual M1-25, the oldest recorded *P. canadensis* at 450 days old.
