Properties evaluation of silorane, low-shrinkage, non-flowable and flowable resin-based composites in dentistry

Rodrigo Maia, Rodrigo S Reis, Andre AFVM Moro, Cesar Perez, Bárbara Pessôa, Katia Dias

(Purpose) This study tested the null hypothesis that different classes of direct restorative dental materials: silorane-based resin, low-shrinkage and conventional (non-flowable and flowable) resin-based composite (RBC) do not differ from each other with regard to polymerization shrinkage, depth of cure or microhardness. (Methods) 140 RBC samples were fabricated and tested by one calibrated operator. Polymerization shrinkage was measured using a gas pycnometer both before and immediately after curing with 36 J/cm² light energy density. Depth of cure was determined, using a penetrometer and the Knoop microhardness was tested from the top surface to a depth of 5 mm. (Results) Considering polymerization shrinkage, the authors found significant differences (p<0,05) between different materials: non-flowable RBCs showed lower values compared to flowable RBCs, with the silorane-based resin presenting the smallest shrinkage. The low shrinkage flowable composite performed similarly to non-flowable with significant statistical differences compared to the two other flowable RBCs. Regarding to depth of cure, lowshrinkage flowable RBC, were most effective compared to other groups. Microhardness was generally higher for the non-flowable vs. flowable RBCs (p < 0.05). However, the values for low-shrinkage flowable did not differ significantly from those of non-flowable, but were significantly higher than those of the other flowable RBCs. (Clinical Significance) RBCs have undergone many modifications as they have evolved and represent the most relevant restorative materials in today's dental practice. This study of low-shrinkage RBCs, conventional RBCs (non-flowable and flowable) and silorane-based composite - by in vitro evaluation of volumetric shrinkage, depth of cure and microhardness - reveals that although filler content is an important determinant of polymerization shrinkage, it is not the only variable that affects properties of materials that were tested in this study.

26 ABSTRACT

27 (Purpose) This study tested the null hypothesis that different classes of direct restorative dental 28 materials: silorane-based resin, low-shrinkage and conventional (non-flowable and flowable) resinbased composite (RBC) do not differ from each other with regard to polymerization shrinkage, depth 29 of cure or microhardness. 30

31 (Methods) 140 RBC samples were fabricated and tested by one calibrated operator. Polymerization O³² shrinkage was measured using a gas pycnometer both before and immediately after curing with 36 33 34 35 36 37 38 J/cm² light energy density. Depth of cure was determined, using a penetrometer and the Knoop microhardness was tested from the top surface to a depth of 5 mm.

(Results) Considering polymerization shrinkage, the authors found significant differences (p<0,05) between different materials: non-flowable RBCs showed lower values compared to flowable RBCs. with the silorane-based resin presenting the smallest shrinkage. The low shrinkage flowable composite performed similarly to non-flowable with significant statistical differences compared to the two other flowable RBCs. Regarding to depth of cure, low-shrinkage flowable RBC, were most effective 39 compared to other groups. Microhardness was generally higher for the non-flowable vs. flowable 40 41 RBCs (p<0.05). However, the values for low-shrinkage flowable did not differ significantly from those 42 of non-flowable, but were significantly higher than those of the other flowable RBCs.

(Clinical Significance) RBCs have undergone many modifications as they have evolved and represent 43 44 the most relevant restorative materials in today's dental practice. This study of low-shrinkage RBCs, conventional RBCs (non-flowable and flowable) and silorane-based composite - by in vitro evaluation 45 of volumetric shrinkage, depth of cure and microhardness – reveals that although filler content is an 46 important determinant of polymerization shrinkage, it is not the only variable that affects properties of 47 materials that were tested in this study. 48

49

50 **INTRODUCTION:**

When dental resin-based composite (RBC) is light cured, stresses develop as a result of the polymerization contraction that accompanies setting, and they may be transferred to the bonded margins of the restoration¹⁻⁵. The magnitude of these potentially damaging stresses is a function of certain characteristics of the material, such as its composition (particularly the filler concentration), the reaction kinetics and the degree of conversion of the polymeric matrix¹⁻⁴.

The filler content of each RBC is directly related to the mechanical properties and wear resistance of the polymerized product. High volume (%) of different fillers are fundamental to minimizing shrinkage of the composite during polymerization⁶. As the filler content influences both the elastic modulus and volumetric shrinkage, the amount of filler present in an RBC is a major determinant of polymerization contraction stress⁷, which ultimately affects the integrity of the restoration margin¹⁻³.

Flowable RBCs differ from their conventional ("non-flowable") counterparts in that they contain substantially less (as much as 25% by weight) filler than conventional RBC⁸, and several studies have 62 shown significant differences in the elastic modulus and volumetric shrinkage between materials of 63 these two classes^{2,9}. Although the high volumetric shrinkage that characterizes flowable composite 64 65 materials may lead to high stress values, it is possible that their low elastic modulus could compensate 66 to some degree for the stress buildup, by helping to maintain the marginal seal and integrity of the 67 restoration². Although flowable RBCs generally have a lower elastic modulus than their non-flowable 68 counterparts, in some cases the elastic modulus may not be low enough to provide significant stress 69 relief, as has been observed in studies evaluating unfilled resins¹.

Efforts to overcome clinical deficiencies of RBCs have led to the development of new matrix materials¹⁰. Siloranes have been suggested as alternatives to methacrylates as components of the RBC polymer matrix, due to their hydrophobicity and low polymerization shrinkage¹¹⁻¹². Siloranes are hybrid systems that contain both silorane and oxirane-based monomers. The individual components of the base resin silorane combined provide two main advantages: low polymerization shrinkage, due to ring opening of the oxirane monomer; and increased hydrophobicity, due to the nature of siloxane species. This system compensates for contraction-induced stress by opening of the oxirane ring during polymerization. The advantage of the hydrophobicity of this restorative material is that it leads to lower absorption of pigments present in the diet, and may reduce the potential for the adhesion of oral biofilms¹². Additionally, silorane monomers produce RBC systems with better biocompatibility and margin integrity, as well as lower water absorption and solubility relative to methacrylate-based RBCs¹³.

The aim of this study was to measure and compare polymerization shrinkage, depth of cure, and Knoop microhardness (KHN) among low-shrinkage to conventional (non-flowable and flowable) RBCs. The tested hypotheses are that: Silorane and low- shrinkage RBCs will present lower polymerization shrinkage; overall shrinkage of the conventional flowable and non-flowable RBCs is related indirectly to their filler content volumes; and low-shrinkage RBCs will have the greatest depth of cure. Therefore this *in vitro* study tested the null hypothesis that different restorative materials: low-shrinkage, conventional (non-flowable and flowable) RBCs and silorane not differ from each other with regard to polymerization shrinkage, depth of cure and microhardness.

90

91 METHODS AND MATERIALS

92 Materials selection and specimen preparation

In this study, seven restorative dental materials (**Table 1**) of A2 / U shade were selected to minimize the effects of colorants on the light polymerization. All samples were fabricated and tested by one calibrated operator. Materials were evaluated for percentage of filler volume and matrix monomer variation within the major categories of restorative RBC: conventional non-flowable (C), 97 flowable (F) or low-contraction (L). Regarding to the material type based on the filler size, 2 different 98 groups are present in this study: Nanofilled and Mycro-hybrid RBCs.

99

101

က 103

100 **Polymerization shrinkage**

Ten samples per group (n=70) were fabricated by placing the material in a 4 mm diameter by 2 mm height stainless steel molds. After the molds were filled, they were placed into a calibrated gas 102 pycnometer AccuPycTM 1340, Micromeritics[®], and the volume was measured before and after light 104 105 06 07 08 curing. Accuracy was ensured by measuring the volume of each specimen five times. Photopolymerization was performed by using a glass slide (2mm thickness) on top of the mold to support the polywave LED tip (Ultra-Lume LED5 at 600 mW/cm², Ultradent, South Jordan, UT, USA) delivering 36 J/cm² (600 mW/cm² as measured with a LED radiometer 910726, Kerr, Orange, CA, USA) of light energy to each specimen to ensure that all brands and ranges of materials were completely cured.

110

109

111 The polymerization shrinkage was calculated using the equation:

 $PS = \underline{V_i - V_f} \times 100$ 112

Vi

113

where PS is the polymerization shrinkage (in %), V_i is the volume of unpolymerized RBC and V_f is the 114 115 volume of polymerized RBC.

116

Depth of cure 117

118 There is disagreement over the best depth of cure evaluation for RBCs. Among the available tests, 119 those assessing the degree of conversion, microhardness and scraping are the most reliable¹⁴. 120 Independent of the test used, the depth of cure needs to take into account the depth at which the 121 transition between the glassy and rubbery state of the resin matrix occurs¹⁵.

The depth of cure was determined using a circular stainless steel split mold (6mm diameter by 5mm height). Ten samples per group (n=70) were prepared by using the same light curing unit and the amount of energy described previously. A Microtester (Instron Corporation, Model No. 4206) was used as a penetrometer, according to the methodology of Harrington and Wilson (1993)¹⁶. Immediately after light curing, the molds were inverted such that the unexposed surface (bottom) faced the penetration needle. Pulses of a 12.5N force (1250 grams) were applied using a 0.5mm diameter needle, at a rate of 1 mm/min, to the middle of the bottom, and the depth of penetration was measured digitally at this point. Depth of cure was calculated using the formula: Depth of cure = Depth of mold - Depth of penetration.

32 Knoop microhardness (KHN)

After depth of cure was measured, the same specimens (n=70) were subjected to testing of KHN using a Digital Microhardness Tester (Matsuzawa Co., Ltd. Model no. MMT-X7 Toshima, Kawabe, 134 Japan). The top, light-exposed surface of each specimen was placed directly below the Knoop diamond 135 indenter, and a 500g load was applied using the indenter, with a dwell time of 15 seconds. The 136 indentation on the top surface was measured at 100X magnification. The KHN corresponding to each 137 indentation was computed by measuring the dimensions of the indentation and using the formula KHN 138 = 14. 2 X (F/d²), where F = test load in Newtons; d = longer diagonal of an indentation (in mm). After 139 140 determining the KHN at the top surface, the split stainless steel mold was opened and KHN values of 141 the side surfaces of the RBC specimens were measured, at 1-mm intervals and working from the top 142 surface down to the level determined as the depth of cure of the RBC sample, using the testing 143 parameters described above. The bottom value for KHN was then recorded.

149

145 Statistical analysis

Statistical analysis was performed using a one-way analysis of variance (ANOVA) and a post-hoc test of Student-Newman-Keuls (SNK) to segregate the materials into groups of similar behavior.0.05 was considered the cutoff for significance.

Signature for the second secon

The results obtained in the present study are displayed in **Table 2.** Included are mean values (p<0.05) and for the degree of polymerization shrinkage, depth of cure and KHN for each RBC. One-way ANOVA indicated that in each test at least one RBC produced statistically significant differences (p<0.05) from the others.

Regarding to:

1) Polymerization shrinkage, the statistical analysis for the seven composite resins revealed statistically significant differences. FP90 (which is based on the resin silorane) showed the lowest value for shrinkage, followed by the non-flowable RBCs (Tetric N Ceram, Filtek Z350XT and Esthet-X HD). SDR represents an intermediate group, with lower values of shrinkage than the other flowable RBCs (FZ350F and TNF).

2) Depth of cure, the RBCs fell into three distinct groups. SDR exhibited the highest depth of cure.
A group of flowable RBCs formed the second group. The non-flowable RBCs represent the third
group.

3) Knoop microhardness, values for the seven composite resins varied widely. As expected, the
highest values for hardness at the top surface were exhibited by the non-flowable RBCs. Moreover,
when the KHN values at the bottom were evaluated, SDR had the highest value.

169 **Discussion**

The results obtained in this analysis led to rejection of the stated null hypothesis, with the tested RBCs showing distinct qualities with regard to polymerization shrinkage, depth of cure and microhardness. The composition of an RBC determines its physical properties in polymerized form. In this study, variations in the polymeric matrix and the filler concentration of new RBCs gave rise to mechanical properties that could prove clinically advantageous over those of the conventional, goldstandard RBCs that were tested. RBCs that are characterized by lower shrinkage and greater depth of cure and by similar hardness at both the top and bottom surface could improve on the current bulkfilling techniques.

Given that volumetric shrinkage is directly related to the organic matrix of the composite resin, it was expected that SDR and silorane-based resins would shrink less than conventional methacrylatebased RBC¹². In addition, the amount of filler particles is related to polymerization shrinkage; non-181 flowable RBCs, which have more filler than their flowable counterparts, typically shrink less during 182 polymerization than do flowable $RBCs^3$. This emphasis on shrinkage is important; when high it may 183 contribute to a restoration's failure by affecting the marginal integrity, and possibly also lead to postoperative sensitivity¹⁷. This study corroborates that volumetric shrinkage ascends for the tested 184 materials in the following order: silorane-based resin, non-flowable RBCs, and flowable RBCs. 185 Nevertheless, SDR presented values of volumetric shrinkage that were very similar to those of non-186 flowable ones and significantly lower than those for other flowable RBC tested. Its inability to improve 187 188 on the non-flowable materials with respect to shrinkage may be due to the fact that the low contraction 189 of the resin monomer could not completely compensate for the lower percentage of filler (44%) in this RBC. 190

Flowable RBCs typically have a greater depth of cure than their non-flowable counterparts. This is because polymerization at depth is directly related to the filler's particle size and dispersion, with smaller size and greater dispersion promoting differences in scattering of the light through the material¹⁴. SDR presented statistically significant increase in depth of cure up to 3mm. This is an improvement over all of the RBCs studied²⁰, though it is also less than the 4mm advertised by the manufacturer⁵. However, other materials also failed to meet the depth-of-cure criteria (above 2mm thickness). This may be due in part to the fact that depth of cure is influenced by RBC shade.

Knoop microhardness was used as a second method to assess the depth of cure in this study, based on the discovery by Flury et al., in 2012¹⁹ that for bulk-fill materials the ISO 4049 method overestimated depth of cure compared to its determination by microhardness tests. The evaluation of top and bottom KHN, and of the percentage reduction, revealed that the flowable RBCs generally produced lower levels of microhardness at the top. The exception was SDR, whose top KHN was significantly higher. Regarding bottom-surface KHN, SDR had the highest mean values, regardless of viscosity, among the materials evaluated in this study. Notably, the ratio of the KHN at the top vs. bottom of the specimen was the lowest in the case of SDR. This fact could be related to the higher depth of cure obtained in the present study.

207

208 CONCLUSIONS

- 209 The following conclusions may be drawn:
- 210 1- The silorane-based resin (FP90) performed as observed in previous studies, exhibiting the least
 211 polymerization shrinkage among the RBCs tested here.
- 212 **2-** The low shrinkage flowable composite (SDR) performed similarly to non-flowable with
- significant difference compared to the other flowable RBCs.

- 214 3- All materials tested presented statistical significant differences for microhardness from the top 215 and from the bottom.
